Tests for cyanogen.—In all simple combinations as, for example, in solution of hydrocyanic acid, the cyanogen may be detected by the following methods. Solution of nitrate of silver produces a white curdy precipitate soluble in boiling nitric acid, and decomposed when heated in the dry state with separation of metallic silver. The addition of small quantities of solutions of caustic potash or soda, protosalt of iron, and persalt of iron, causes a precipitate of oxides of iron; by the addition of hydrochloric acid the oxides of iron in excess are dissolved, whilst prussian blue of characteristic colour remains suspended in the liquid. Another very delicate test consists in adding a few drops of strong sulphuric acid to a small portion of the suspected substance contained in a watch-glass, over which is inverted another watch-glass moistened with yellow sulphide of ammonium. If cyanogen is present the sulphuric acid is set free under the form of hydrocyanic acid, and this with the sulphide of ammonium forms sulphocyanide of ammonium ($NH_4,\,CyS_2$). Excess of sulphide of ammonium must now be got rid of by heating the upper watch-glass till quite dry, at a temperature not exceeding that of boiling water. The addition to it when cold of a drop of a dilute solution of sesquichloride of iron causes the production of an intense red colour (sulphocyanide of iron). This mode of detecting cyanogen may be adapted to the two preceding tests, the upper watchglass being of course in the one case moistened with solution of nitrate of silver, and in the other with the mixed solutions of the salts of iron. In endeavouring to detect the presence of hydrocyanic acid, the peculiar odour of the faintest trace of that substance should ever be remembered as a valuable aid.

Cyanogen and *oxygen* form no les than six compounds, all having the same per-centage composition but differing markedly, and some considerably, from each other. It will be convenient to describe them in separate articles. [CYAMELIDE; CYANIC ACID; CYANILIC ACID; CYANURIC ACID; FULMINIC ACID; FULMINURIC ACID.] Their relation to each other may be thus expressed:—

Cyanuric acid . . .	$C_6H_3N_3O_6$	$= 3HO,\,C_6N_3O_3$	$= 3(HO,\,CyO)$
Cyanilic acid . .	$C_6H_3N_3O_6$	$= 3HO,\,C_6N_3O_3$	$= 3(HO,\,CyO)$
Fulminuric acid . .	$C_6H_3N_3O_6$	$= HO,\,C_6H_2N_3O_5$	$= 3(HO,\,CyO)$
Fulminic acid . .	$C_4H_2N_2O_4$	$= 2HO,\,C_4N_2O_2$	$= 2(HO,\,CyO)$
Cyanic acid . . .	$C_2H\ N\ O_2$	$= HO,\,C_2N\ O$	$= (HO,\,CyO)$
Cyamelide . . .	$C_2H\ N\ O_2$	$= HN,\,C_2O_2$	$= (HO,\,CyO)$

Cyanogen and *nitrogen.* [CYANAMIDE.]

Cyanogen and *chlorine* form three isomeric compounds, the first gaseous, the second liquid, and the third solid.

Gaseous chloride of cyanogen ($CyCl$) is obtained by passing chlorine gas into strong hydrocyanic acid, or by conveying chlorine over moist cyanide of mercury excluded from the light. It may be collected over mercury.

This compound is a colourless gaseous body, extremely pungent, and soluble in water, alcohol, and ether. At zero it forms a colourless crystalline mass, and this at 5° melts into a liquid which boils at 11°. When subjected to pressure of four atmospheres it assumes a liquid form; and if long kept it is converted into the solid chloride. It is composed of 1 equivalent of chlorine 35·5 + 1 equivalent of cyanogen 26 = 61·5. Spec. grav., 2·124.

Liquid chloride of cyanogen (Cy_2Cl_2) is produced when cyanide of mercury is exposed to the action of chlorine in direct sunlight. It is a liquid, boiling at 61° Fahr., and solidifying to a mass of crystals at 19°. Equivalent, 123.

Solid chloride of cyanogen, chlorocyanic acid (Cy_3Cl_3). This compound is obtained when anhydrous hydrocyanic acid is exposed to chlorine gas acted upon by the sun's rays; hydrochloric acid being also formed. It has the form of long colourless needles, which have a powerful and disagreeable odour. The crystals fuse at 284°, and sublime unaltered at a higher temperature. It dissolves in alcohol and ether without decomposing; but when heated with water it is decomposed into cyanuric and hydrochloric acids. It was probably owing to the formation of these acids that chloride of cyanogen was originally supposed to possess acid properties; and hence the name of chlorocyanic acid. It may be considered as composed of 3 equivalents of chlorine 106·71 + 78 = 184·71. Vapour density, 6·39.

Cyanogen and *bromine,* and

Cyanogen and *iodine,* form solid combinations. They are obtained on distilling cyanide of mercury with bromine or iodine.

Cyanogen and *sulphur* form a *bisulphide* (CyS_2). This substance cannot be obtained in the free state. In its combinations it partakes of the nature of cyanogen itself, forming compounds in the same manner as an elementary body. For this reason it is usually considered to be a compound radical, and is called *sulphocyanogen;* its symbol as such is (Scy). The salts that it forms with the metals very much resemble in constitution the corresponding compounds with cyanic acid, the oxygen in the latter being replaced by sulphur.

Hydrosulphocyanic acid ($HCyS_2$), or *sulphocyanide of hydrogen* (H, Scy), may be regarded as hydrated cyanic acid ($HO,\,CyO$), in which the oxygen is substituted by sulphur, and may be written thus,—

(HS, CyS). It is usually however expressed by the formula (H, Scy), and the other sulphocyanides by the general formula (M, Scy). This acid may be isolated by exposing subsulphocyanide of mercury to a current of sulphuretted hydrogen. It is a colourless liquid. By exposure to a low temperature it solidifies to a mass of crystals. It is unstable, soon decomposing into hydrocyanic acid and *hydropersulphocyanic acid* ($H_2Cy_2S_3$).

Sulphocyanide of potassium (K, Scy) is formed by fusing together sulphur and cyanide of potassium, or by heating in a covered crucible at a dull red heat a mixture of 46 parts of dried ferrocyanide of potassium, 32 of sulphur, and 17 of pure carbonate of potash. The cooled mass is digested in water, filtered, the filtrate evaporated to dryness, and the residue digested in hot alcohol. On cooling, the liquid deposits the salt in beautiful crystals.

Other sulphocyanides are obtained by double decomposition with the potassium salt. The sulphocyanides of barium, calcium, and iron are soluble; those of mercury, lead, and silver are white insoluble precipitates. Soluble sulphocyanides give, with ferric salts, an intense red solution, owing to the formation of persulphocyanide of iron. This reaction is characteristic.

Chlorine and nitric acid act upon sulphocyanic solutions, producing a yellow precipitate, the composition of which has not been satisfactorily determined. By heat this precipitate is altered into a substance called by Liebig *crude mellon*. [MELLON]. *Melam* is the name given by Liebig to the residue of the destructive distillation of sulphocyanide of ammonium. [MELAM.]

Cyanogen and *selenium* form combinations corresponding in composition and properties to the sulphocyanic compounds.

Metallic Derivations of Cyanogen.—Cyanide of potassium forms double salts with the cyanides of cobalt, copper, iron, chromium, platinum, and iridium. It is usually assumed that in these salts the potassium is combined with electro-negative compound salt-radicals, to which have been given the names *cobalticyanogen*, *cuprocyanogen*, *ferrocyanogen*, *chromicyanogen*, *platinocyanogen*, *platinidcyanogen*, and *iridiocyanogen*. Some of these are monobasic, some dibasic, and others tribasic. They form, with hydrogen, a well-marked series of acids. The following list of these acids, with their formulæ, will at once indicate their constitution :—

Hydroplatinocyanic acid	$H, Pt\,Cy_2$
Hydroiridiocyanic acid	$H, IrCy_2$
Hydroplatinidcyanic acid	H_2, Pt_2Cy_5
Hydroferrocyanic acid	H_2, Fe_2Cy_3
Hydroferridcyanic acid	H_3, Fe_2Cy_6
Hydrocobalticyanic acid	H_3, Co_2Cy_6
Hydrochromicyanic acid	H_3, Cr_2Cy_6
Hydrocuprocyanic acid	?

The methods of preparing the most important of the above acids will be found described in the articles on the different metals that enter into their composition.

By the replacement of the hydrogen in these acids by an equal number of equivalents of a metal, a numerous class of salts is formed, some members of which are largely used in the arts. Thus, by substituting the two equivalents of hydrogen in hydroferrocyanic acid by two of potassium, we obtain ferrocyanide of potassium (K_2, $FeCy_3$, or K_2Fcy), the common yellow prussiate of potash. From hydroferridcyanic acid (H_3, Fe_2Cy_6, or $H_3, Fdcy$) we derive ferridcyanide of potassium (K_3, Fe_2Cy_6, or K_3Fdcy), ordinary red prussiate of potash. For details of the preparation of the principal of these salts, see the various metals.

Hydronitroferrocyanic acid, or *hydronitroprussic acid* ($H_2, Fe_2Cy_5NO_2$), is produced when binoxide of nitrogen (NO_2) is passed through a solution of hydroferridcyanic acid. The decomposition that takes place is thus expressed :—

$$\underbrace{H_3Fe_2Cy_6}_{\text{Hydroferridcyanic acid.}} + \underbrace{NO_2}_{\text{Binoxide of nitrogen.}} = \underbrace{H_2, Fe_2Cy_5NO_2}_{\text{Hydronitroprussic acid.}} + \underbrace{HCy}_{\text{Hydrocyanic acid.}}$$

Hydronitroprussic acid may be obtained in prismatic crystals of a deep red colour, containing two equivalents of water. *Nitroprussides*, containing two equivalents of a metal in the place of the hydrogen in the acid, are readily formed. The sodium salt crystallises in fine ruby-red prisms; the barium salt in beautiful octohedra. For details of the preparation of these salts, see papers by Playfair in the 'Philosophical Transactions,' 1849 and 1850.

The characteristic test for nitroprussides is the production of a beautiful purple colour on the addition of an alkaline sulphide. Traces of sulphur on the one hand, or of a nitroprusside on the other, may thus be detected with certainty; the colour is however very fugitive.

CYANOMETER, from the Greek words *κυανός* (blue) and *μέτρον* (a measure), is an instrument which was invented by M. de Saussure for the purpose of enabling an observer to *measure* the intensity of *blue* colour in the sky.

It is well known that the visible heavens, when free from clouds, appear to have a blue tint which gradually increases in intensity from the horizon towards the zenith, that the blueness is more intense by night than by day, and that on the tops of mountains the colour is sometimes so deep as to be almost black. These appearances depend partly on the different extents of atmosphere which the rays of light have to pass through, and partly on the quantity of water which the air holds in solution. It has been supposed that the gaseous fluid, air, is of a *blue* colour; the colour being so slight as to be seen only when we look through large masses of air; and that it is to this cause that distant mountains owe their peculiar bluish tint. When, as towards the zenith, the atmospheric space traversed by the light is comparatively small, the violet and blue rays are transmitted to the earth in abundance; while, towards the horizon, the spaces passed through being greater and being charged with vapours, the violet, the blue, and even the green rays are intercepted, the remaining colours only of the spectrum being transmitted: it must, however, be added that the colour of the sky is affected by the terrestrial particles which are occasionally raised in the atmosphere; and also by the reflections of light from terrestrial objects, particularly from naked rocks and from masses of snow or ice. The colour of the sky being thus, in some measure, an indication of the state of the atmosphere with respect to exhalations and the reflections of light from the earth's surface, it is of importance to ascertain with some precision the intensity of that colour.

The cyanometer, as formed by the inventor, consists of a circular plate or ring, of metal or pasteboard, on the surface of which, about the circumference, is a band divided by radii into fifty-three equal compartments. One of these is white, and those which follow in succession are coloured with blue of different degrees of intensity, from the most faint to the deepest which can be produced; the rest of the compartments are coloured with mixtures of Prussian blue and ivory black, and gradually increase in darkness to the last division, which is quite black.

In using the instrument, the observer, who should be in the open air, holds it up between himself and that part of the sky of which he intends to ascertain the colour; and this part should be such that, while the face of the instrument is strongly enlightened, the direct rays of the sun may not fall upon it: on turning the plate or ring in its own plane, till there is brought directly before the observed part of the sky that compartment which, to the eye, appears to be exactly equal to it in intensity of tint, the number of the compartment will express the required intensity of the blue colour in that part of the sky.

In order to form a scale of numbers for the tints, M. de Saussure placed against a wall a piece of white paper, on which was a circular black spot, about one-seventh of an inch in diameter, and receded from it till the spot ceased to be visible; he then laid on paper a tint produced by Prussian blue, so diluted that, at a distance from it equal to that at which the black spot became invisible, the tint could not be distinguished from a perfect white. This tint was marked No. 1. The next deeper colour was produced by diluting the Prussian blue till, at an equal distance, the tint ceased to be distinguished from that of No. 1, the latter being near the eye: this was marked No. 2; and each of the succeeding numbers up to No. 53 was determined in like manner by a comparison of the corresponding tint with that which preceded it on the plate.

Arago invented a cyanometer, which acts on the same principle as his photometer. The *latter* instrument is thus formed: Two lenses are placed, one on the other, so as to form coloured rings about the point of contact, which, as is well known, are seen as well by transmitted as by reflected light, the one set being complementary to the other. These two series of rings neutralise one another mutually when the two lights which form them, and which fall simultaneously on the lenses, are of equal intensity. His cyanometer is an extension of this principle. It is formed of a tube closed at one end by a plate of rock-crystal cut perpendicularly to its axis, and, at the end nearest the eye, by a doubly refracting prism. Among the colours which this apparatus gives, when polarised light traverses it, and the prism is turned on its axis, is the peculiar blue colour of the sky, which varies in intensity according to the proportion of polarised light admitted by turning the prism.

Suppose now that this polariscope be directed upon a piece of white paper, and that between the paper and the plate of rock-crystal there is placed a pile of plates of glass, which can be moved in an angle, so as to vary their inclination, and make the bright light from the paper more or less polarised. The blue colour seen in the instrument goes on increasing in intensity with the inclination of the pile, until it appears the same as that of the region of the sky which we are observing. The measure of this cyanometric tint is then given by the inclination of the pile, and if the pile be composed of the same number of plates, and the same kind of glass, the observations made with this instrument will be of course comparable.

CYANOSIS, or BLUE DISEASE, is a condition of the system which comes on as the result of a malformation of the heart, which allows the venous and arterial blood to mingle in the system. In the fœtus the circulation is of such a kind as to prevent the blood flowing from the placenta passing through the lungs, and this is done by a communication between the pulmonary artery and the aorta—the *ductus arteriosus*; and an opening between the right and left ventricle—the *foramen ovale*. After birth these two communications between the right and left side of the heart are normally closed, but it occasionally happens that one, or both, passages do not close at birth or that they open again in after life. The consequence of this malformation is that the venous blood passes to the left side of the heart without undergoing its proper amount of oxygenation in the lungs. The effect of this abnormal mixture of the two bloods is not to destroy life immediately, but to produce a series of symptoms, the most prominent of which is a blueness of the skin, constituting the disease called cyanosis. This is not an unfrequent occurrence, and according to the extent of the communication between the two sides of the heart will be the intensity of the disease. Sometimes the feebleness and derangement of the system causes death within a few hours after birth; in other cases persons have been known to attain mature age labouring under this affection.

The effect of this malformation, according to its degree, is to diminish the nutrition of the body, and to produce general weakness and exhaustion. The functions of the heart and lungs are interfered with, and there is frequently a rapid intermitting pulse, with attacks of difficulty of breathing. The blueness of the skin is increased during these attacks. There is generally coldness of the skin from the imperfect nature of the respiratory changes which go on in the body. There is also a tendency to dropsical effusion in various parts of the body.

In this disease little can be done to effect a cure. The great object is to alleviate any distressing symptoms which may arise.

CYANOXALIC ACID. [Uric Acid.]

CYANURENIC ACID, an acid found in the urine of the dog. It much resembles uric acid, but differs in being soluble in hydrochloric acid. It is obtained from the tenacious deposit that forms when the urine of the dog is set aside for some time. That substance is dissolved in lime-water, and sufficient hydrochloric acid added to neutralise the lime; cyanurenic acid then separates in the form of small colourless needles. It is insoluble in alcohol, is sublimed by heat, and is then soluble in alcohol. It forms salts with bases, some of which are crystalline.

CYANURIC ACID ($3(HO, CyO) + 4Aq.$, or $3HO, C_6N_3O_3 + 4Aq.$). This acid was discovered by Scheele in the distillation of uric acid; more lately Serullus obtained it by another process, and described it under the name of cyanic acid; and lastly, Wöhler and Liebig examined its constitution and properties.

This acid is formed under various circumstances, as by the decomposition of solid chloride of cyanogen by water, the decomposition of soluble cyanates by dilute acid, and the distillation of uric acid, &c.

In order to prepare it, the best process seems to be to dissolve dry melam [Melam] with a gentle heat in concentrated sulphuric acid; the solution is to be poured into 20 or 30 parts of water, and the mixture is to be kept for several days, at a temperature near ebullition, or until small portions yield no white precipitate with ammonia. The solution is then to be evaporated to its crystallising point, and the crystals obtained are to be purified by recrystallisation.

Cyanuric acid forms rather small colourless prismatic crystals, which are efflorescent, losing at ordinary temperatures the whole of their water of crystallisation. It is very slightly soluble in cold water, and requires 24 parts of boiling water to dissolve it; it is inodorous, has but little taste, and reddens litmus but feebly. It is a remarkably permanent substance, being soluble without decomposition in concentrated sulphuric or nitric acid, though when heated in them it is eventually decomposed.

According to Liebig, the crystallised acid consists of 3 equivalents of cyanogen 78, 3 equivalents of oxygen 24, 7 equivalents of water 63, equivalent = 165: 3 equivalents of the water constitute the acid a hydrate, and 4 equivalents are water of crystallisation. It combines with 3 equivalents of base to form cyanurates, and is therefore what is termed a tribasic acid. By exposure to a very high temperature 1 equivalent of hydrated cyanuric acid is decomposed into 3 equivalents of hydrated cyanic acid. Urea is by heat converted into cyanuric acid and ammonia.

CYBELE. [Rhea.]

CYCLAMIN. [Arthanitin.]

CYCLE, which means nothing but circle (κύκλος), has an arbitrary use in chronology. Certain of the cycles, or recurring methods of denoting time, which are in common use, are called cycles, to the exclusion of the rest. The principal of these, if not the only ones, are the Metonic cycle [Meton, Biog. Div.; Calippus, Biog. Div.], the solar cycle, and the cycle of Indiction. But the natural cycles, such as the revolutions of the sun and moon, are not called cycles; nor even some of the artificial ones, such as the Julian *period*. It would be useless to retain this artificial and confused distinction. Under the distinctive words Meton, Biog. Div., Indiction, &c., the reader will find the origin of each method of reckoning; while in the article Period of Revolution, he will see a table of the lengths and commencements of all the cycles, natural and artificial, whether called cycle, period, year, day, or month.

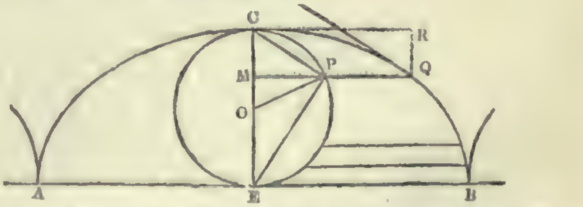
CYCLOGRAPH, or ARCOGRAPH, is an instrument for drawing arcs of circles without centres, and is used in architectural and engineering drawing, when the centres are too distant to be conveniently accessible. One such contrivance, which however does not produce perfectly circular arcs, is noticed under Compasses. Bricklayers and masons, when they wish to strike an arc for the tops of doors and windows, have recourse to a very simple mode of accomplishing the object, by driving a nail into the wall at each extremity of the intended arc, and then nailing two straight laths or rods together at such an angle that while their external sides or edges are in contact with the nails driven in the wall, their apex or meeting point shall touch the crown of the required arch. A tracing point in the apex will then describe the required arc. The same plan may be adopted in drawing on paper, substituting pins for the nails, and a piece of stout cardboard, cut to the required angle, for the laths. Mr. Rotch's Arcograph, described in the 'Transactions' of the Society of Arts, vol. xxxix. pp. 49–51, is an instrument consisting of two rules connected together by a joint which forms a socket for a pencil, and furnished with two quadrant-shaped pieces of brass, sliding upon one another, by which the rules may be set to any required angle, and secured by clasps. This instrument is used in the same way as the laths above described, and it affords the means of measuring, by the graduation of one of the quadrants, the degrees contained in the arcs described by it. Mr. Alderson's *Curvilinead*, described in the forty-fourth volume of the same work, pp. 151–156, is another instrument on the same principle, but of more perfect construction, in which the pencil may be projected beyond the apex of the angle for the purpose of drawing a second arc parallel with the first. This second arc is not mathematically correct, but, when on a small scale, it is sufficiently so for all ordinary purposes.

The *Centrolinead* of Mr. Peter Nicholson, described in the thirty-second and thirty-third volumes of the 'Transactions' of the above Society, pp. 67-70 and 69-81, is an instrument acting on the same principle, although its chief use is, not as a cyclograph, but as an instrument for drawing lines converging to a distant and inaccessible point. It may be compared to a T-rule in which the transom consists of two pieces adjustable to any required angle with each other, and the centre of which, answering to the apex of the cyclographs above described, is precisely on a line with the fiducial or drawing edge of the stem or long limb of the rule. The instrument being once adjusted to the required angles, and having its angular transom laid against two fixed pins, just like the angle of a cyclograph, any number of converging lines may be drawn by it as readily as parallel lines drawn by a common T-rule, with its transom sliding against the edge of the drawing-board.

Another instrument rewarded by the Society of Arts, and described in the thirty-fifth volume of their 'Transactions,' pp. 109-112, under the name of a *Curvograph*, was contrived by Mr. Warcup for copying or transferring curved lines, or describing them originally, of any required curvature, by means similar to those adopted in the instrument represented under Bevel. The adjustable ruler itself consists of a thin pliable slip of whalebone, and the adjusting ribs, answering to the screws *ff*, in the figure above referred to, instead of being screwed, are merely secured in any required position by the pressure of wedges acting upon small pieces of cork inserted in the ruler or stock through which they pass.

CYCLOID (κυκλοειδὴς, like a circle), a name very incorrectly given to the curve which is traced out by any point of a circle rolling on a straight line. Thus while the wheel of a carriage revolves, each nail on the circumference describes a succession of cycloids; more correctly, a succession of branches of *one cycloid*. We might also here describe the various curves made by the points of circles which roll inside or outside of other circles, &c. &c. But as the cycloid stands apart from all the rest, both in simplicity and historical notoriety, we shall here confine ourselves to this one curve alone, and refer the rest to the head Trochoidal Curves.

If we suppose a circle to roll on a straight line, it is obvious that the centre will advance in every moment through a length equal to the portion of the circumference which is brought in contact with the line on which the circle rolls. That is,



supposing C, the point now highest on the circle, to be the one whose path is to be traced, then, by the time the mere rotation would have brought this point to P, the whole system will have been carried forward through a length PQ equal to the arc CP. Hence follows a very simple mode of conceiving the form of a cycloid: at every point P imagine a line PQ parallel to AB and equal to the arc CP; the extremities of all these lines will be in the cycloid. The arc AC, through which the point on the circle rises from the line AB to its highest position, is similar and equal to the arc CB through which it descends. In the diagram we see small parts of the preceding and succeeding cycloids.

The principal properties of the cycloid are as follows:—

1. PQ is equal in length to the *arc* CP.
2. The tangent at Q is parallel to the *chord* CP.
3. The arc CQ is twice the chord CP, and the whole arc ACB is four times CE, the diameter of the generating circle.
4. Complete the rectangle CQR; the area CQR is equal to the

circular area O P M, and the whole area A C B is three times that of the generating circle.

5. The curvature at Q is the same as that in a circle whose radius is twice E P, and the involute and evolute (see these terms) of a cycloid are both cycloids of the same magnitude.

6. If the figure be reversed, so that C is the lowest point of the cycloid, and A and B the highest points; then, no friction being supposed, and the cycloid being of resisting matter, a small weight placed at Q will take the same time to slide to C, whatever the point Q may be. Hence all the arcs of the cycloid are said to be *synchronous*.

6. On the same supposition as in the preceding, a weight will slide from B to Q in a shorter time than in any other curve which can be drawn between B and Q. Hence the cycloid is called the *brachystochron*.

Let θ be the angle C O P (in theoretical units) [ANGLE], $CM = x$, $MQ = y$, $OP = a$, then we have the following equations:—

$$x = a\,(1 - \cos\theta)$$
$$y = a\,(\theta + \sin\theta)$$

from which the properties of the curve may be deduced.

If, instead of measuring P Q from P, we had carried it forward from M, then Q would have described a curve known by the name of the *companion to the cycloid*, but which is in truth a *curve of sines*. [SINES, CURVE OF.]

The history of the cycloid is remarkable from the contests which it produced, and the manner in which the names of Galileo, Descartes, Mersenne, Pascal, Roberval, Wallis, and others, appear in connection with it. But there would be little use in giving an abstract of history on points of no material use, and the interest of which depends on the light in which a detailed account, and nothing less, would place the state of science of the 17th century. Galileo was certainly the first who attempted the investigation of the properties of the cycloid, as appears from a letter to Torricelli, written in 1639. (See Montucla, 'Hist. des Math.' vol. ii. p. 52, &c.)

CYCLOPÆDIA. [DICTIONARY.]

CYDER. [CIDER.]

CYGNUS (the swan), one of the old constellations of Aratus, who refers it to the fable of Leda, as does Hyginus; but the latter gives another fable of the same kind. The bright star (Deneb), α Cygni, may be seen on the meridian at eight o'clock in the beginning of October; the bright stars in Aquila, Lyra, and Cygnus form a remarkable triangle.

The principal stars are as follows:—

Character.	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
κ	1	6628	4
β^1	6	6690	3
δ	18	6779	3
θ	13	6734	4
γ	37	7022	3
(ι)	41	7067	4
α	50	7171	2
ε	53	7204	3
χ	54	7213	4
υ	58	7277	4
ξ	62	7333	4
ζ	64	7368	3
τ	65	7385	4
σ	67	7398	4
ρ	73	7503	4
π^1	80	7560	4

CYLINDER, in mathematics (κύλινδρος), a name given generally to the surface formed by a straight line which moves parallel to itself, whatever may be the guiding curve; but frequently confined to the common definition, which supposes the straight line to be of finite length, and to move round the circumference of a circle, keeping always at right angles to its plane. We shall extend this a little, and treat of the cylinder which has an oval for its base, and the moving line at right angles to the plane of the base, whence the cylinder is called a *right* cylinder.

The cylinder may be considered us a cone, of which the apex is at an infinite distance; and many of the general notions in the article CONE may be applied to it.

The content of a cylinder (in cubic units) is the number of square units in the base multiplied by the number of linear units in the altitude. Thus the cylinder being circular, the base having a radius of 10 feet, and the altitude being 7 feet, the number of square feet in the base is 100 × 355 ÷ 113, or 314·159, which, multiplied by 7, gives 2199·113, the number of cubic feet in the cylinder. To find the number of square units in the surface, multiply the number of linear units in the circumference of the base by that in the altitude. Thus in the preceding case the number of feet in the circumference of the base is 20 × 355 ÷ 113, or 62·8318, which, multiplied by 7, gives 439·8226, the number of square feet in the cylindrical part of the surface, exclusive of its two terminating planes. [PRISM, SUBCONTRARY.]

CYLINDRICAL LENS. [LENS.]

CYMAMETER. This name has been given to a contrivance, registered by Mr. Fenn a few years ago, for making copies of the outlines of capitals, cornices, mouldings, and other architectural figures. Many years earlier, a curious plan was adopted for taking a mould of the human face, by enclosing a large number of thin steel wires in a frame; pressing it gently and gradually, so that one end of every wire should touch the face, and thus form a die or intaglio of wires, the reverse of the face. Mr. Fenn seems to have conceived his cymameter as an extension of this plan. It consists, essentially, of a large number of very thin laths or plates, all of equal length, and placed one on another. When one end of these laths is pressed against a moulding or other device, the other end assumes a corresponding position; the laths which press against a convex surface jut out more at the other end than those which press against a concave surface; insomuch that the outer extremities of all the laths form collectively a type of the moulding or device.

CYMBALS (κύμβαλον), metallic musical instruments of percussion, which are traceable to the remotest ages of antiquity, and, with no great change in form, are still used by the moderns. They are always in pairs, are made of brass, and, according to Greek sculptures and medals, anciently took, as their name imports, a more cup-like shape than at present. Servius says that the cymbals were consecrated to Cybele—that is, were employed by her priests—because they represented the two celestial hemispheres which surround the earth. They are now nearly flat, about twelve inches in diameter, the central part sunk in, and at the back of the sunken portion is a strap, by which each instrument is held. The sound is produced by striking them more or less violently together, and in the open air they produce a very martial effect, but are entirely out of place in the theatre and concert-room. Into the latter, indeed, they have not yet often intruded, but in modern theatrical music they take a prominent part when the composer has to make up by noise what he wants in genius and taste.

CYMENE. [CAMPHOGEN.]

CYMIDINE ($C_2H_{13}N$). An artificial organic base, analogous to aniline. It may be formed by the action of sulphide of ammonium upon nitrocymole ($C_{20}H_{13}NO_4$).

CYMI'NUM CYMI'NUM, *Medical Properties of.* This annual umbelliferous plant (the generic name of which is most commonly spelt Cuminum, which mode is correct if it be a mere Latinised form of the Arabian word Qamoùn, but incorrect if it be a reduplication of the Greek κύμινον) is native in Egypt, Æthiopia, &c., and was cultivated by the ancients in Palestine, as it is by the moderns in Malta, Sicily, and India. The fruit (improperly termed seed) is the officinal part. Externally it is of a grayish yellow colour, and is larger than those of caraway or anise. The seed within more readily separates from the pericarp than happens with most other umbelliferous fruits. It is distinguished from others by having the ridges (juga) prolonged into a point at the summit of the fruit. The primary ridges are five, filiform, and furnished with very fine prickles; the secondary are four, prominent and prickly. Beneath each of these is one vitta. The odour is strong, aromatic, and rather unpleasant; the taste is warm, bitter, and disagreeable. The odour and taste are mainly due to a volatile oil which is more abundant in this fruit than in most umbelliferous plants: one pound yields half an ounce of this oil, according to some; while ten pounds yield only three ounces and a half, according to others. Notwithstanding this large quantity of oil, the fruits are frequently eaten by insects. The oil is pale yellow, but speedily becomes brownish, very limpid, of a specific gravity of 0·975. This consists of two distinct oils, one a carbo-hydrogen, belonging to the terebinthinate series; the other an oxygenated oil, or hydruret of cumyl. (Pereira.) The odour is, like that of the fruit, disagreeable, and the taste is acrid. When old it becomes acid, and according to Chevallier contains succinic acid.

The disagreeable odour of cumin seems to have gradually discarded it from medicine for man, and restricted its use to veterinary medicine. Its employment in this way may be a relic of its ancient repute, for the Israelites esteemed it highly as a remedy for cattle after the bites of insects. (Lady Callcott's 'Scripture Herbal,' p. 124.)

Still it is a potent carminative, and was esteemed by Cullen the best of this class of remedies, a preference to which the very large portion of essential oil it contains justly entitles it. It was reported also discutient and diuretic. In the former quality it was employed as a plaster. It was reckoned one of the semina 4 calida majora. In the north of Europe it is still much used as an addition to bread and ragouts. It enters into the composition of many curry-powders, but should be introduced into these in very small quantity. In Germany a sort of liqueur or aromatic water is distilled from the fruits, useful as a carminative, called kummel-wasser. The seeds of the nigella sativa are, in the same country, called black cummin.

CYMOLE ($B_{20}H_{14}$). This substance, met with in oil of cumin, and which also occurs in coal-tar oil, is further formed by the action of anhydrous phosphoric acid, or of chloride of zinc or camphor.

$$\underbrace{C_{20}H_{16}O_2}_{\text{Camphor.}} = \underbrace{C_{20}H_{14}}_{\text{Cymole.}} + 2HO$$

It is a colourless liquid of an agreeable odour. It is lighter than water, and boils at 347° Fahr. Fuming sulphuric acid forms with it a copulated acid.

Sulphocymolic acid ($C_{20}H_{14}S_2O_6$). When heated with moderately strong nitric acid it is changed into toluic acid ($C_{16}H_8O_4$) and nitroluic acid ($C_{16}H_7(NO_4)O_4$). By the action of a mixture of sulphuric and nitric acids, it is converted into *binitrocymole* ($C_{20}H_{12}(NO_4)_2$) a substance which crystallises in iridescent rhombic plates.

CYNAPINE, an alkaloid said to be found in the false parsley (*Æthusa cynapium*). Its composition is unknown.

CYNENE ($C_{24}H_{18}$). A hydrocarbon oil, obtained by distilling the essence of semen-contra (*Artemisia castra*) from anhydrous phosphoric acid. It is a very fluid colourless oil, soluble in ether, but insoluble in water. Its specific gravity is ·825, and it boils about 345° Fahr.

CYNICS, the name of a sect of Greek philosophers who were produced by the school of Socrates, and were so called according to one interpretation of the word (*κυνικοί*, dog-like) from their snarling disposition, though it is possible that the name may have been derived from the gymnasium called Cynosarges, in which Antisthenes, the founder of this school, used to lecture. [ANTISTHENES, in BIOG. DIV.] Their doctrines were the exact opposite of those of the Cyrenaics, who were also an offshoot of the Socratic philosophy. [CYRENAICS.] They held that virtue was not only the highest but the only object at which men ought to aim, and that most of the sciences and arts, as they do not tend to make men virtuous, but sometimes on the contrary interfere with the attainment of it, are unprofitable and pernicious. The true philosopher, according to their notions, was he who could discard all the comforts and charities of life and triumph over his bodily wants, so as to be enabled to live only for virtue without any interruptions either to the contemplation or the practice of it. The result of these principles was great strictness of morals, and voluntary penances worthy of the fanaticism of an eastern dervise; and as long as these characteristics were coupled with ability in the professors and consistent philosophy in what they taught, the sect maintained its place by the side of other philosophical systems, and some members of it, for instance Antisthenes and Diogenes, deserved and obtained great celebrity. [DIOGENES, in BIOG. DIV.] At length, however, the morality of the Cynics degenerated into the most shameless profligacy (see the case of 'Crates and Hipparchia' in Diogen. Laërt. vi. § 97), and they became so disgusting from their impudence, dirty habits, and begging, that they ceased to be regarded with any respect, and the sect dwindled away into obscurity. Of their speculative opinions we know very little: indeed it does not appear that they had any theories, except on the science of logic. The great merit of the Cynic philosophy was that it paved the way for the establishment of Stoicism, which succeeded and superseded it, just as the philosophy of Epicurus supplanted that of Aristippus. The connection of this school with the philosophy of Socrates appears to have consisted in their developing the idea of science as applied to morality (to which object the labours of Socrates were mainly directed), but they did so to the exclusion of all those other principles which Socrates admitted as useful adjuncts, and his sneers at the austerity and affected negligence of Antisthenes may be taken as a proof of the low opinion which he entertained of this narrow application of his doctrines. (Diogen. Laërt., vi., § 8; ii., § 36.) The classical reader will find in Lucian's 'Cynicus' an attempt to justify some of the peculiar views of this school, especially in regard to their neglect of the conveniences of life, though it is not to be supposed that Lucian was inclined to the Cynical philosophy, for he elsewhere ridicules it. (See the 'Lapithæ' and the 'Vitarum Auctio.' See also Ritter's 'Geschichte der Philosophie,' Hegel's 'Geschichte der Philosophie,' and G. H. Lewes's 'Biographical History of Philosophy.')

CYNODIN. A non-azotised crystallisable body of unknown composition, found in dog-grass (*Cynodon dactylon*).

CYNOSU'RA (*κυνὸς οὐρά*, the tail of the dog), a name given to the lesser Bear. According to Aratus and Hyginus, Cynosura was one of the nymphs of Mount Ida, who nursed Jupiter. But it is at least as probable that before the Greeks adapted their mythology to the constellations, they had from some oriental source the habit of figuring Ursa Minor as a dog, and that the tail of the dog was the pole star. [URSA MINOR.] Many persons may probably know this word only from the two lines of Milton's 'Allegro'—

> Where perhaps some beauty lies,
> The Cynosure of neighbouring eyes.

These lines may have puzzled some readers, though the reference to the pole star and the property of the magnet gives the image a degree of fitness for poetry which the etymology of the word alone would hardly suggest.

CYRAMETURIC ACID. [CYANOGEN.]

CYRENA'ICS, a school of philosophers among the Greeks, who derived their name from the birth-place of their founder Aristippus. [ARISTIPPUS, in BIOG. DIV.] Like the Cynics, their doctrines were a partial development of those of Socrates; but the view they took of their predecessor's philosophy was quite different from the Cynical. [CYNICS.] The only particular in which the two sects agreed with the original system and with one another was that they all three made virtue consist in knowledge; in other words they were all three attempts to awaken and develop the idea of science; but while the Cynics considered all sublunary enjoyment and most branches of knowledge as impediments to the knowledge, and consequently, according to Socrates, to the practice, of virtue, the Cyrenaics, on the other hand, were not contented with the mere knowledge of the good as a general term, but sought for it in the separate particulars, and deemed him to have performed his proper functions most consistently with his nature who had succeeded in amassing the greatest number of particular good things. In regard to the idea of science, they did not look upon it as a speculative conception, but as a merely empirical result, as the aggregation of successive experiences; in other words, not as an intuition but as a combination of perceptions; and while Plato, and in some measure the Cynics also, placed the *summum bonum* in the attainment, by means of dialectics, of the abstract idea of the good, the Cyrenaics placed it in the collection of the greatest number of agreeable perceptions, and the true philosopher, according to them, was one who actively, methodically, and successfully carried on the pursuit of pleasure. Consequently, as agreeable perceptions were continually to be sought as good and the contrary to be avoided as bad in themselves, perception of sensible objects became the criterion of all knowledge and the object of all action, and therefore truth both theoretical and practical. (Sextus Empir. 'adv. Mathematicos,' vii., § 191–200.) The chief successors of Aristippus were Theodorus, Hegesias, and Anniceris. Theodorus perceived the necessity for some principle, in addition to the mere collection of agreeable sensations; for without some effort of the understanding to determine which of many gratifications was to be preferred, it would be impossible, he thought, to obtain the maximum of gratification; and he therefore set the understanding over the senses as a regulating and restraining faculty. He is said to have been banished from Athens for denying the existence of the gods. (Diog., Laërt., ii., § 97.) Hegesias, following in the steps of Theodorus, insisted still more than he did upon the inadequacy of the senses as the criteria of the desirable, and at last even went so far as to assert that nothing was in itself either agreeable or the contrary, and that life and everything in life should be a matter of indifference to the wise man. In this assertion of the principle of indifference he made an approach to the doctrines of Epicurus and the Stoics in the point in which those two opposite systems met. Cicero tells us ('Tuscul. Disput.,' i., c. 34) that his book called ἀποκαρτερῶν caused so many suicides that he was forbidden by one of the Ptolemies to lecture on the worthlessness of life. In the philosophy of Anniceris and his followers the original principles of the Cyrenaics were quite lost, and though he also, in a popular way recommended the pursuit of the agreeable, he denied that it depended in any way upon mere sensible impressions, for that the wise man might be happy in spite of all annoyances; that friendship was to be sought, not for the sake of any immediate advantage to be derived from it, but on account of the good-will which it generated; and that for a friend's sake a man should encounter even annoyances and troubles. (Diog. Laërt. ii., § 96, 97.) These are the doctrines of a mere popular morality, and can hardly be ascribed to one school more than to any other. It will be remarked by every one that the original tenets of this school were very similar to those of Epicurus; indeed, with the exception of the atomic system which he borrowed from Democritus and Leucippus, the two systems differed only in this: the Cyrenaics placed the great object of man in the positive and active pursuit of the agreeable, while Epicurus made it consist in a perfect rest of mind and in freedom from pain; for he considered the agreeable as something merely negative, as the pleasing harmony produced by exemption from all passion and appetite. The philosophy of Epicurus may therefore be considered as the successor, in one point of view, of the system of Aristippus.

(See also Ritter's *Geschichte der Philosophie*; Hegel's *Geschichte der Philosophie*; and G. H. Lewes's *Biographical History of Philosophy.*)

CYSTIN ($C_{12}H_{12}N_2O_8S_4$?), *Cystic Oxide.* A crystalline substance constituting a very rare form of human calculus. It is neutral, fusible by heat, and furnishes by destructive distillation a very fetid ammoniacal water. It is insoluble in water and in alcohol, but the fixed alkalies and their carbonates dissolve it readily. Cystin is also soluble in many of the acids.

CYTISIN. A non-azotised bitter substance, extracted from the *Cytisus laburnum*. It appears to be identical with cathartin. [CATHARTIN.]

CZAR, or TZAR, the Russian title of the monarch of Russia. Some have supposed it to be derived from Cæsar or Kaisar, but the Russians distinguish between Czar and Kesar, which last they use for emperor. The sovereign of Russia styles himself also Autocrat of all the Russias. It is only since the time of Peter the Great that the title of emperor has been given to him by the senate, and afterwards by the other courts of Europe. Before Peter's time, the sovereign of Russia was styled grand duke in European diplomacy. The consort of the czar is styled czarina.

D

D, which occupies the fourth place in the Hebrew alphabet and those derived from it, is the medial letter of the order of dentals or palato-dentals. It readily interchanges with those of the same organ. The German language and the English offer an abundance of examples.

1. *D* in German corresponds to *th* in English, as *dein*, thine; *denk-en*, think; *du*, thou; *dieb*, thief; *donner*, thunder; *dorn*, thorn; *durch*, through; *tod*, death; *bruder*, brother; *erde*, earth; *leder*, leather; &c. And on the other hand, *th* in German, which however is not pronounced as among us, corresponds to *d* in English, as *thau*, dew; *thal*, dale; *thaler*, dollar; *thu-n*, do; *that*, deed; *theil*, dole and deal; *roth*, red; *noth*, need; *muth*, mood.

2. *T* in German to *d* in English, as *tag*, day; *taub*, deaf; *taube*, dove: *tief*, deep; *traum*, dream; *tod*, death; *brot*, bread; *breit*, broad; *wort*, word; *bart*, beard.

3. *D* in Latin to *z* or *zz*, or *s* final in German, and *t* in English, as *decem*, *zehen* or *zehn*, ten; *digitus*, *zehe*, toe; *duo*, *zwey*, two; *dingua*, (the same as *lingua*), *zunge*, tongue; *dens* (*dent*) *zahn*, tooth; *cor* (*cord-is*), *herz*, heart; *duc-ere*, *zieh-en*, tug: *doma-re*, *zahm-en*, tame; *sud-or*, *schweiss*, sweat; *pes* (*ped-is*), *fuss*, foot; *ed-ere*, *ess-en*, eat; *clud-ere*, *schliess-en*, shut; *od-it*, *hass-en*, hate; *quod*, *was*, what; *id*, *es*, it; *grandis*, *gross*, great.

4. *D* is interchangeable with *l*, and this most freely. Compare the Greek forms Οδυσσευς, Πολυδευκης, δαψιλης, δακρυ-ω, δε-ω, δολιχος, with the Latin *Ulixes*, *Pollux*, *lapsilis*, *lacruma*, *liga-re*, *longus*. In the Greek language itself compare δειδω with δειλος, δαλος with δᾳς (δᾳδ-ος); and in the Latin, *sella*, *scala*, *mala*, *valla*, with the verbs *sede-o*, *scand-o*, *mand-o*, *vad-o*. *Vesidia* and *Digentia*, two small streams of ancient Italy, are now called respectively *Versiglia* and *Licenza*. So the Italians say either *edera* or *ellera* for ivy; and the Latin *cauda*, a tail, is in Italian *coda*, in Spanish *cola*. But one of the most remarkable instances of this change exists in the words *eleven* and *twelve*, in both of which the *l* has grown out of a *d* in *decem*. In the same way, while the Greek has δεκα for ten, the Lithuanian prefers *liku*; and of two Sanscrit dialects, one has *dasan*, the other *lasan*, for the same numeral. The people of *Madrid* call themselves *Madrilenos*. The language of *Madagascar* is *Malagash*.

5. *D* attaches itself to the letter *n*. Thus we find Gr. τειν-ω, and Lat. *tend-o*, stretch; Lat. *canis*, Eng. *hound*; Lat. *sonus*, Eng. *sound*; Lat. and Gr. root μεν or *men*, Eng. *mind*; Ger. *abend*, Eng. *even* or *even-ing*; Ger. *donner*, Eng. *thunder*; Ger. *niemand*, Lat. *ne-mon*, Eng. *no-man*. And our English term *husband*, is a corruption of *house-man* (Lat. dominus). This *d* is particularly apt to insert itself after an *n* when an *r* follows. Thus from the Latin *ciner-is*, *gener*, *tener*, come the French *cendre*, *gendre*, *tendre*. And the latter language has the futures *viendrai*, *tiendrai*, where analogy would have led to *venir-ai*, *tenir-ai*.

6. *Di* before a vowel is changed into a *g* or *j*, as *Dianus* or *Janus*, the god of light (dies) in Roman mythology; *Diana* or *Jana*, the goddess of light. So *Diespiter* and *Jupiter* are the same name. The Latin *hodie* is in Italian *oggi*. Sometimes a *z* is preferred to a *g*, especially in the Greek, Italian, and German languages. In the Greek, for example, ζα is used for δια; hence ζαω, *vivo*, and διαιτα, are connected, and the same town on the African coast is called indifferently *Hippo Zarytus* or *H. Diarrhutos*. So in England we write the name of a certain town *Odiham*, and call it *Ojam*.

7. *Du* before a vowel is changed into *b* or *v*. [See B.] With this principle is connected the change of *d* into *v*, in the words *suavis*, *suadeo* and ἀδυς, *clavis* and *claudo*, and the river *Suevus* or *Oder*.

8. Instances occur where *d* is interchanged with both the other medials; with *b*, as in Latin *barba*, *verbum*, English *beard*, *word*; with *g*, as in the Greek Δημητηρ from γη μητηρ, πηδος, "the beech," as well as φηγος, and in the two names of the African city, Καρχηδων and *Carthago*. One may often hear in the mouths of children *dood* for *good*, and *do* for *go*.

9. *D* when flanked by vowels often disappears in the transition of words from Latin into French. Compare *Melodunum*, *Ludovicus*, *vadum*, *vādis*, *medius*, *fides*, *nudus*, *cauda*, *assidere*, *videre*, with *Melun*, *Louis*, *gué*, *vas*, *mi*, *foi*, *nu*, *queue*, *asseoir*, *voir*.

For the forms of the letter D see ALPHABET.

D as a Roman numeral signifies five hundred. It is more correctly written IↃ. [NUMERALS.]

DA CAPO ("from the head," or "beginning"), an Italian musical term, signifying that the first part, or strain, is to be repeated, and to conclude at the sign of the pause (𝄐), or at the word *fine*. The phrases in use are, *Da Capo al fine*, and *Da Capo al segno*; that is, "From the beginning (or over again) to the *fine*," or "to the sign." This term is abbreviated by the letters D. C.

DACTYL is the name of a metrical foot consisting of a long and two short syllables, as the Latin word *littora*; or of an accented syllable followed by two unaccented, as *gallery*.

DACTY'LICS. To this term belong all those metres which consist of a repetition of dactyls or equivalent feet. The long syllable may be the first in the line, as it is in the heroic verse of Homer; or it may be preceded by one or two short syllables. Thus the modern anapæstic verse is strictly a dactylic metre, as—

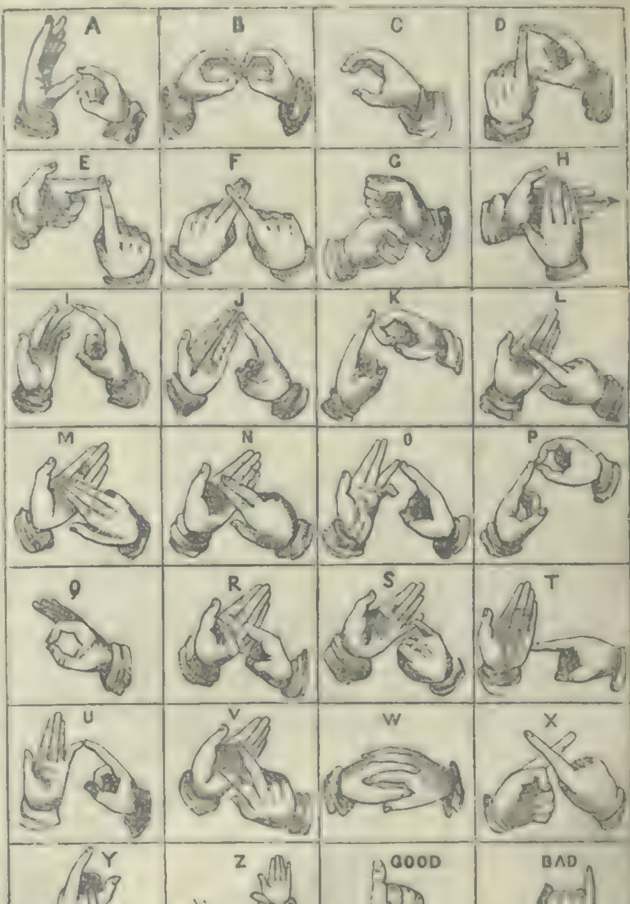
> "If he ha'd any fau'lts, he has le'ft us in dou'bt."

Of the dactylic metres the most common are the hexameter, which, as its name implies, consists of six feet [HEXAMETER], and the pentameter, of five feet.

The dactylic metre often alternates with trochaic measures. Such is the case in the sapphic and alcaic stanzas.

DACTYLO'LOGY. The simple art of communicating ideas by spelling words with the fingers is called dactylology. The positions which the fingers are made to assume correspond to the alphabetic characters of a language, and the series of alphabetic signs is perhaps better known under the name of the manual alphabet. The chief, and the most useful application of dactylology is in the instruction of the deaf and dumb. In the various institutions for this class of persons, dactylology is almost universally employed. The letters may be formed by the two hands, or with only one hand: a two-handed alphabet is used in the English institutions; on the continent of Europe, and in America, the one-handed alphabet is employed. Either of them may be learned by an hour's practice; they are often taught to the deaf and dumb, in conjunction with the written alphabet, in a few days.

TWO-HANDED ALPHABET OF THE DEAF AND DUMB.



Dactylology must not be confounded with the natural language of the deaf and dumb, which is purely a language of mimic signs. We mention this because some persons have misunderstood the office and overrated the value of finger-talking; imagining that all deaf and dumb persons naturally understand language, and converse with their fingers, and that, by acquiring the manual alphabet, they can communicate with them. Such persons should bear in mind that the deaf are shut out from all spoken languages; that before they can use or understand a written or spoken language, they must learn it; and that such an acquirement is made, under their disadvantages, by a very slow process. To the deaf and dumb under instruction, dactylology is useful as a means of communication between them and their teacher; at first, in such select language as the pupil understands, or as may be readily explained by mimic signs or other auxiliaries. As the pupil advances in the knowledge of words and their collocations, this mode of communication becomes more satisfactory, and at length he can use it to converse on all ordinary subjects with the accuracy of writing and with much greater rapidity.

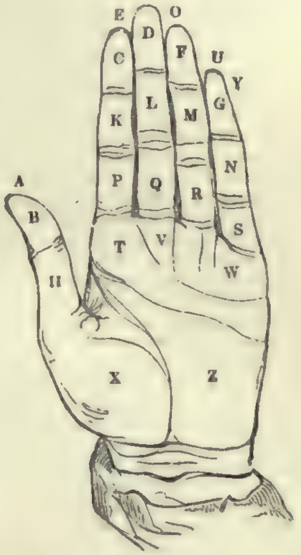
Degérando has clearly and fully explained the use and value of this very simple art. ('De l'Education des Sourds-Muets,' Paris, 1827.) He says dactylology is to alphabetic writing what that is to speech. Formed upon writing as its model, it represents it precisely as writing represents words. But in this connection between dactylology and writing, the reciprocal utility of the two orders of proceeding is at the same time the reverse of what we have remarked in the connection between writing and speech. In fact, the office of dactylology consists in giving to writing that moveableness which speech enjoys, and which the first loses in the fixedness of depicted characters. Dactylology is writing set free from its material dress, and from those conditions necessary for the employment of the pen or pencil; it carries with itself these instruments; it is thus ready in all familiar conversations; it affords help at all times and in all places. It is thus that dactylology is little more than a toy for those who already possess, in speech, a means of communication more easy and more appropriate to all circumstances. It is thus also that it becomes an essential resource to those who are deprived of speech, to whom it renders a portion of those advantages, supplying for them writing, and giving it in some manner a new extension. However, dactylology is far from affording all the advantages of speech, while it loses a portion of those which are peculiar to the privilege of writing. On the one hand it is much less rapid than speech; it is unfurnished with that expression which belongs to the human voice—of that infinite diversity which the soul finds within for pourtraying all the sentiments which affect it; it has nothing of that harmony, that secret charm, that power of imitation of which speech is so capable; its employment, besides, obliges the suspension of all business and all action. On the other hand, it has none of that durability which renders writing so favourable to the operations of reflection; it is not able to exhibit its signs but after a successive manner; it cannot preserve in composing, as writing does, those vast pictures which the inventive faculty embraces simultaneously, and subsequently surveys, in every sense, with perfect liberty. Dactylology shares in some of the inconveniences of speech, and in some of those of writing; it is as fugitive as the first, it is as complicated in its forms as the second. (Vol. i., pp. 259, 60.)

The manual alphabet has been employed as a medium of intercourse between the deaf and dumb, and blind persons; it is also commonly used by the former when they have to converse in the dark. As the art addresses itself to the sense of touch, as well as to that of sight, it is easy to touch another person's hands, who is acquainted with the hand alphabet, in such parts or positions as to enable him to read the words or sentences thus conveyed. Bulwer, one of the earliest writers on the instruction of the deaf [BULWER, in BIOG. DIV.], was fully aware of the advantage of manual alphabets in their instruction; and it seems strange that he did not invent one, or ascertain and make known the merits of one, of which he thus writes:—

"A pregnant example, of the officious nature of the touch, in supplying the defect or temporall incapacity of other senses, we have in one Master Babington, of Burntwood, in the county of Essex, an ingenious gentleman, who, through some sicknesse, becoming deaf, doth, notwithstanding, feele words, and, as if he had an eye in his finger, sees signes in the dark; whose wife discourseth very perfectly with him by a strange way of arthrologie, or alphabet contrived on the joynts of his fingers; who, taking him by the hand in the night, can so discourse with him very exactly; for he feeling the joynts which she toucheth for letters, by them collected into words, very readily conceives what she would suggest to him." ('Chirologia, or the Natural Language of the Hand,' p. 106.)

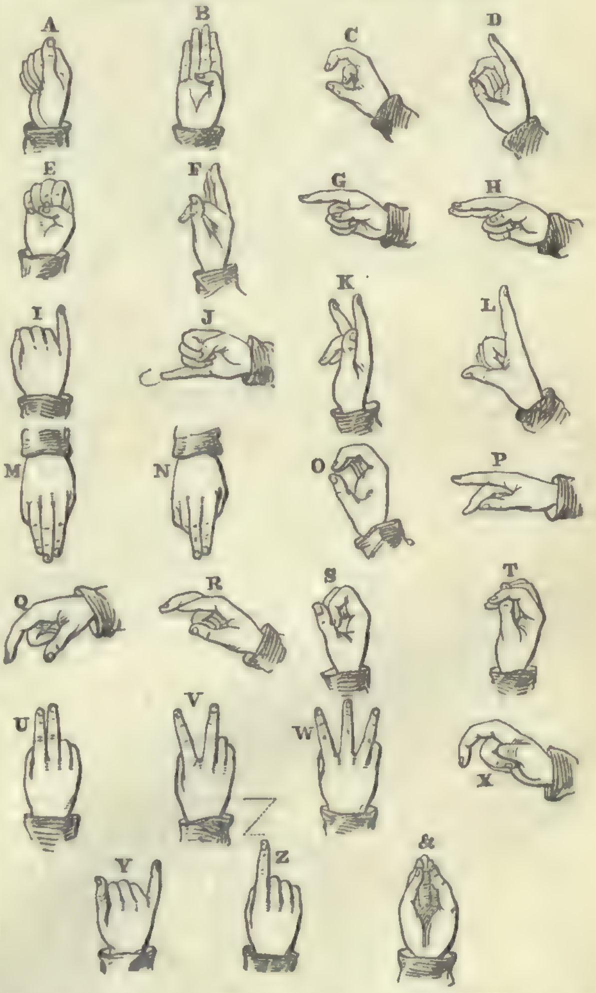
Perhaps the first manual alphabet which was published in England was that of Dalgarno, the most intelligent author on the subject of the instruction of the deaf and dumb next to Bulwer; he published it in 1680. As few copies of his work are now to be met with, we shall give his hand-alphabet, and accompany it by as much of his own explanation as seems necessary for understanding his views on dactylology. "After much search and many changes, I have at last fixt upon a finger or hand-alphabet according to my mind; for I think it cannot be considerably mended, either by myself or any other (without making tinker's work), for the purposes for which I have intended it; that is, a distinct placing of and easy pointing to the single letters; with the like distinct and easy abbreviation of double and triple consonants."

"The scheme (I think) is so distinct and plain in itself, that it needs not much explication, at least for the single letters, which are as distinct by their places as the middle and two extremes of a right line can make them. The rules of practice are two. 1. *Touch the places of the vowels with a cross touch with any finger of the right hand.* 2. *Poynt to the consonants with the thumb of the right hand.* This is all that I think to be needful for explaining the scheme, so far as concerns the single letters."



This was probably the finger-alphabet from which our present two-handed one was derived; some similarities may be traced in them, particularly in the places for the vowels. The one-handed alphabet

ONE-HANDED ALPHABET FOR THE DEAF AND DUMB.



was invented in Spain, and appears to have been first published in Bonet's work. [BONET, in BIOG. DIV.]

At a conference of principals of institutions for the deaf and dumb, held at the Yorkshire Institution at Doncaster, on July 28th, 1852, a paper was read by Mr. Hopper, headmaster of the institution for the deaf and dumb at Birmingham, 'On the One-Handed Alphabet,' in which he thus stated its claims for more general adoption :—

"It appears to possess every advantage that can be claimed for the two-handed alphabet. The various positions by which it represents the letters can be assumed as rapidly, and with as much facility, as those employed in the two-handed method. It has besides many advantages over its rival. It is more distinct. The upright, downward, and horizontal positions of the hand, enable one to distinguish easily several of the letters at a distance. The signs for the vowels being as distinct as those for the consonants, prevents the confusion occasioned by the difficulty of observing which finger has been touched in rapid spelling with both hands. By using the right hand, when conversing with a person placed on one's left, and *vice versâ*, what is spelled can be easily read by those to whom it is addressed; while, in employing both hands, the positions of the fingers are less obvious to the person spelled to than to the person who spells. The employment of one hand only, is in itself a great advantage; for the other hand is left at liberty to hold an umbrella, the reins in driving, and to perform a number of offices that it would be tedious to enumerate. In walking, besides allowing those in conversation to be linked, it does not attract the attention of strangers so much as the two-handed system of spelling. In sickness, too, it requires comparatively very little effort to hold out one hand, and to spell with it. I have found that our deaf-mutes, though more practised in the two-handed method, invariably use the other alphabet when confined to bed."

"Should it be considered by the teachers present desirable to substitute the one-handed alphabet for the alphabet now generally used, I would suggest that the greatest possible uniformity, both as to the positions of the hand and of the fingers should be observed."

A short discussion followed the reading of the paper from which the above extracts are given, which concluded by the expression of a unanimous opinion, that it would be desirable to accustom the pupils in all the institutions to the use of both the manual alphabets.

A dactylology of syllables has been sometimes employed in the instruction of the deaf and dumb. This was one of the means adopted by Pereire, who lived in the middle of the 18th century, and who was more successful in imparting a knowledge of language to his pupils than any teacher who has since cultivated this difficult art. But his modes of teaching were a mystery which he always refused to divulge, and they were lost at his death. In more recent days, M. Recoing has employed syllabic dactylology in conjunction with stenography, and by these means, combined with others more commonly pursued, he conducted the instruction of his own deaf and dumb son with that success which enabled him to convey to his son the words of a speaker as rapidly as they were uttered. M. Recoing published two works on this subject at Paris, in the years 1823 and 1829. A system of alphabetic and syllabic dactylology was also published by Dr. Deleau, the younger, in 1830.

There remains to be noticed another application of finger-language which, in the instruction of the deaf and dumb, is next in importance to alphabetic signs; it is in the designation of numbers, and in the employment of the fingers in the first rules of arithmetic. The ten fingers are the most ready and natural abacus, as they are doubtless the most ancient. That they should early come into use for exhibiting numbers, especially where speech was wanting, may be readily supposed. The only system of manual notation which deserves that name is the one which we shall now describe. It is used in several of the American and English institutions for the deaf and dumb; we consider it perfect, and we believe it has never before appeared in any English publication. Mr. David Seixas, of Philadelphia, improved the Abbé Sicard's signs for numbers, and his plan was used in the institution for the deaf and dumb in that city. The following system was invented by Mr. O. Stansbury, a former superintendent of the New York Institution; it has received a few, perhaps unimportant, modifications, and by it any amount of numbers may be expressed. One hand only, the left is used, and the pupil's right hand is thus left at liberty to record his calculations upon his slate. The nine digits are represented one after another by elevating the fingers of the hand successively, as represented in the annexed illustration.

The thumb represents *one*, the other fingers being closed, the index finger is added for *two*, the middle-finger is raised for *three*, the ring-finger is added for *four*, and the open hand represents *five*; the little finger alone is raised for *six*, the ring-finger is added for *seven*, the middle-finger for *eight*, and the fore-finger is raised to the others for *nine*. Thus far for units. To indicate tens, the position of the hand is changed from perpendicular to horizontal; the thumb is pointed forwards for ten, the thumb and fore-finger for twenty, and so on to ninety. Hundreds are pointed downwards; thus the thumb, fore-finger, and middle-finger pointed downwards represent 300. If 572 be the number to be designated, three positions of the hand are required; the five fingers are pointed downwards for 500, the little-finger and ring-finger are pointed forwards for 70, and the thumb and fore-finger are held upright for two. During these changes the hand is kept in front of the body. To represent thousands, the left hand is placed across the body towards the right shoulder, and the signs which were used in front for units, in this situation, represent thousands; keeping the hand in the same situation and pointing forwards or downwards, tens of thousands or hundreds of thousands are exhibited. By changing the situation of the hand to the left shoulder, and by exhibiting the various positions of the fingers before described, millions, tens of millions, and hundreds of millions are expressed. The same positions, upright, forwards, and downwards, exhibited in other situations, may be applied to the expression of notations to any extent. Though rather complex in description, the whole is most easy and comprehensive in operation. The superiority of this system of manual notation for teaching arithmetic to the deaf and dumb, or for making signals of numbers where silence is necessary, compared with the clumsy resources of figuring the digits in the air, of repetitions of tens by the ten fingers, or even of arbitrary signs, will be at once acknowledged.

The application of this arithmetical dactylology in teaching all the simple rules to the deaf and dumb is very easy; in *addition*, two hands are employed, one for representing the figures added, the other for keeping an account of the results; in *subtraction*, the larger and the lesser number may be shown on the two hands, and the difference afterwards, or the two numbers by one hand, successively, and the difference by the other; in *multiplication*, the factors are shown by different hands by the teacher, and the product required from the pupil; and so with *division*, the product and one factor is shown, and the other factor required. All this can be done without any permanent figuring on slates or tablets, and is better, because more rapid both in explaining principles and in acquiring practice, than the pencil or chalk. At the same time it is chiefly applied in explanations, in early practice, and in mental arithmetic, and can never supersede the usual methods in precision and permanence.

DADO, a term of architecture to express the square die or plinth of the pedestal of a column. It is also used in joinery to express the portion of the wall-decoration of a room comprised between the base-moulding or plinth, and the impost or chair-rail.

DADYL ($C_{20}H_{16}$), is obtained by heating oil of turpentine with lime. [TURPENTINE.]

DAGUERREOTYPE. [DAGUERRE and NIEPCE, in BIOG. DIV.; and PHOTOGRAPHY.]

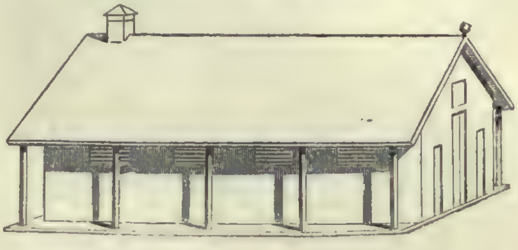
DAHLIN. [INULIN.]

DAIRY, the name usually given to the place where the milk of cows is kept and converted into butter or cheese. The occupation is called *dairying;* and land which is chiefly appropriated to feed cows for this purpose is called a *dairy-farm.*

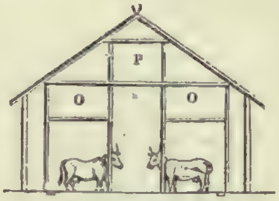
A dairy-house should be situated on a dry spot somewhat elevated, on the side of a gentle declivity, and on a porous soil. It should be on the west or north-west side of a hill if possible, or at least sheltered from the north, east, and south, by high trees. In some countries, where there are natural caverns with an opening to the west, and springs of water at hand, the best and coolest dairies are thus prepared by nature. Artificial excavations in the sides of freestone rocks are sometimes formed for the purpose of keeping milk, and more frequently wine. When no such natural advantages exist, the requisite coolness in summer, and equal temperature in winter, which are essential in a good dairy, may be obtained by sinking the floor of the dairy some feet under ground, and forming an arched roof of stone or brick. In cold climates flues around the dairy are a great advantage in winter; and an ice-house in warm summers is equally useful. But these are only adapted to those dairies which are kept more as a luxury than as an object of profit. In mountainous countries, such as Switzerland, where summers are hot in the valleys, and the tops of the mountains or high valleys between them are covered with fine pastures, the whole establishment of the dairy is removed to a higher and cooler atmosphere, where the best butter and cheese are made. Coolness is also produced by the evaporation of water, an abundant supply of which is essential to every dairy. It is also a great advantage if a pure stream can be made to pass through the dairy, with a current of air to carry off any effluvia, and keep the air continually renewed.

As the milk suffers more or less from being agitated, or too much cooled, before it is set for the cream to rise, the milking-place should be as near as possible to the dairy. The milk may then be brought immediately from the cows. The dairy-house should consist of three distinct apartments below, with lofts and cheese-chambers above. The principal place is the dairy, properly so called, sunk two or three feet below the level of the ground, with a stone or brick bench or table round three sides of it to hold the milk pans. This table should be a little below the level of the outer soil. Air-holes covered with wire should be made in the walls a little above, and on opposite sides of the dairy; and they should have shutters sliding over them to open or shut according to the weather. The floor should be of stone or paving-tiles, sloping gently towards a drain to carry off the water. Great care should be taken that no water stagnates in this drain, which must be kept as clean as the floor of the dairy, and not communicate with any sink, but run out into the open air: a declivity from the dairy is essential for this purpose. If this cannot be obtained, it must run into an open tank, and the water be regularly pumped out. The windows of the dairy should be latticed. Glazed windows may be added for the winter, but they should always be open except in very hot or very cold weather. There may be shutters to close entirely, but this is not essential. If the windows are made like venetian blinds, the light will be excluded without excluding the air. The utmost purity must be maintained in the air of a dairy; nothing should enter it that can produce the slightest smell. No cheese or rennet should be kept in it; and particularly no meat, dressed or undressed. Even the dairy-maid should avoid remaining longer in it than is necessary, and should at all times be extremely clean in her person.

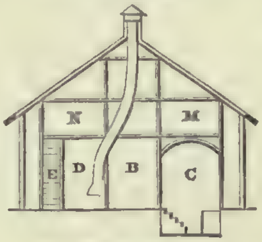
The next important place is a kind of wash-house, in which there is a chimney where a large copper kettle hangs on a crane to heat water in, or milk when cheese is made. In countries where wood is scarce, and pit-coal is the common fuel, a copper may be set in brick-work with a grate under it, as is usual in England. In this place all the utensils of the dairy are kept, and scalded with boiling water every day. It should have an outer door, which may be to the south, and benches outside on which the pails and other utensils may be set to dry and be exposed to the air. Between the two last apartments may be another communicating with both, and forming a kind of vestibule, where the churning may take place; and over them a cheese-room and lofts, or any other useful chambers. A verandah round the dairy is very convenient, or on three sides at least. It shades from the sun, and adds to the warmth in winter; and the utensils may be dried and aired under it even in rainy weather. Gentlemen's dairies are often built expensively, and highly ornamented; but they seldom unite all the conveniences essential to a good dairy, because the architects who plan them are seldom practical farmers. They are generally too far from the cow-houses. A dairy-house placed near a mansion, and at a distance from the farm-buildings, is quite out of its place. In Switzerland and in Holland the cow-house and dairy have a very neat appearance within a short distance from the principal residence. The plan in both countries is very similar; the style of the roof is the chief difference. The plan is taken from the common dairy-farms in Holland, where the farmer and his family live under the same roof with his cows. In the Netherlands, especially in North Holland and Friesland, a cow-house is as clean as any dwelling-house, and the family often assemble and take their meals in it. The following is a description of a cow-house and dairy under one roof, as in Holland: It is a building about sixty feet long by thirty wide, with a verandah running round



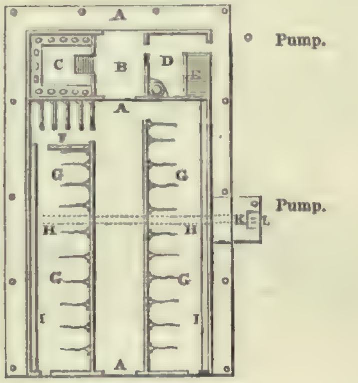
Side View.



Section of the Cow-house.



Section of the Dairy.



Ground Plan.

A, A, A, passage through the cow-house and dairy ten feet wide, paved with bricks set on edge or Dutch clinkers. The food is brought in this passage in a small cart and distributed to the cows; B, part of the above passage closed in with doors and forming a vestibule to the dairy; C, dairy-room, in which only milk, cream, and butter, are kept. It is sunk three feet under the level of the cow-house, and covered with a brick arch; it has one latticed window, and several ventilators, on a level with the place on which the milk vessels are set; D, the room where the utensils are scalded, and where cheese is made; in the corner is a fireplace, with a large kettle or a copper set; E, the stairs to go up to the cheese-room M and loft N; F, calf-pens, in which the calves are tied up to fatten, so that they cannot turn to lick themselves; a small trough with pounded chalk and salt in each pen; O, the place for the cows, without partitions; each cow is tied to two posts by two small chains and two iron rings, which run on the posts. The chains are fastened to a broad leather strap, which is buckled round the neck of each cow; H, H, two sinks, with iron gratings over them, to catch the urine from the gutters I, I, which run all the length of the cow-house on each side; K, the urine tank, vaulted over with a door, L, to clean it out, and a pump to pump up the liquid manure; O, O, in the section are places where the green food or roots are deposited for the day's consumption; P, a hay-loft.

three sides of it. The dwelling is not here attached, as it usually is in common dairies, and the building is not surrounded by a farm-yard: these are the only circumstances in which it differs from that of a common peasant. The dairy-room is sunk below the level of the soil, and is paved with brick. The sides are covered with Dutch tiles, and the arched roof with hard cement. The cow-house, like all in Holland, has a broad passage in the middle, and the cows stand with their heads towards this passage, which is paved with clinkers or bricks set on edge. Their tails are towards the walls, along which runs a broad gutter sunk six or eight inches below the level of the place on which the cows stand. This gutter slopes towards a sink covered with an iron grate, which communicates by a broad arched drain with a vaulted tank, into which all the liquid flows. The gutter is washed clean twice a day before the cows are milked. The cows stand or lie on a sloping brick floor, and have but a small quantity of litter allowed them, which is removed every day, and carried to the dung-heap or to the pig-styes to be more fully converted into dung. Whenever the litter is removed, the bricks are swept clean; and in summer they are washed with water. In Holland the cows' tails are kept up by a cord tied to the end of them, which passes over a pulley with a weight at the other end, as we see practised with horses that have been nicked: thus they cannot hit themselves, or the person who milks them. The manner in which the cows are fastened is worthy of notice: Two slight pillars of strong wood are placed perpendicularly about two feet distance from each other, so that the cow can readily pass her head between them. On each of these is an iron ring, which runs freely up and down, and has a hook in its circumference; two small chains pass from these hooks to a leather strap, which buckles round the neck of the cow. Thus the cow can rise and lie down, and move forward to take her food, which is placed in a low manger before the two pillars; but she cannot strike her neighbour with her horns. The mangers or troughs are of wood, or bricks cemented together, and are kept as clean as all the rest of the cow-house. In Switzerland the cow-houses are similar, but there is also a rack, the back of which towards the passage shuts up with a board on hinges. The Dutch mode supplies more light and air to the middle passage; and as the food is given frequently and in small quantities there is very little waste. The preceding cuts will give a tolerable idea of the whole arrangement. The food is brought in carts, which are driven at once between the cows. What is not wanted immediately is stored above, whence it is readily thrown down before the cows. Thus much trouble is saved, and one man can feed and attend to a great many cows. From November till May the cows never leave the cow-house. In summer, when they are out, if they are in adjacent pastures, they are driven home to be milked, but if the pastures are far off, which is sometimes the case, they are milked there, and the milk is brought home in boats; but this is not thought so good for the butter, which is then always churned from the whole milk, without letting the cream rise. The finest and best flavoured butter is always made from the cream as fresh as possible; and to make it rise well, the milk should be set as soon as it is milked, and agitated as little as possible. The greatest quantity is seldom obtained when the quality is the finest. When great attention is paid to the quality, the milk is skimmed about six hours after it is set; and the cream taken off is churned by itself. The next skimming makes inferior butter. These particulars are mentioned to show the necessity there is of having the dairy as near as possible to the cow-house.

The utensils of the dairy, such as pails, churns, vats, &c., are usually made of white wood, and are easily kept clean by scalding and scouring. Leaden troughs are used in large dairies; and if they are kept very clean by careful scouring, they answer the purpose better than wood. They may be so constructed that the milk may be let off gently before the cream, which is collected by itself. This saves all the trouble of skimming. Brass pans have the advantage of being readily warmed on a chafing-dish in winter. In Devonshire tin or brass pans are frequently used instead of earthenware. There is some danger in the use of brass utensils, though a very little attention will obviate it. It only requires that they should be kept bright, in which case the smallest speck of oxide or verdigris would be perceptible. Glass milk pans are coming into use, and are highly approved. In Holland the milk is invariably carried in brass vessels. Cast-iron pans have been invented, which are tinned inside. They are economical; but there is nothing better or neater than well-glazed white crockery ware, of the common oval form. Some recommend unglazed pans for summer, but they are difficult to keep sweet, as the milk insinuates itself into the pores, and is apt to become sour there.

The most common use of cows is to supply butter and cheese [BUTTER and CHEESE], and sometimes to fatten calves [CALF] for the butcher; but the most profitable dairy is that which supplies large towns with milk. In these dairies the system is different. The cows are mostly kept in stalls, and fed with food brought to them. Some dairymen near London possess several hundred cows, and the arrangement of their establishments is worthy of notice. The cows are bought chiefly in the north, before or after they have calved. They are seldom allowed to go to the bull, but are kept as long as they can be made to give milk by good feeding. When they are dry, they are often already sufficiently fat for sale, or at all events they soon fatten, and are sold to the butcher. A succession of cows is thus kept up, new ones arriving as others are sold off. The women who purchase the milk from the dairyman and carry it about for sale, come for it to the dairy and milk the cows twice a day; and as they well know that the last drop of milk is the richest, the cows are sure to be milked quite dry, an essential thing in a dairy. An accurate account is kept of the quantity which each woman takes, which is paid for weekly. When there is more milk than there is a demand for, it is set, and the cream is sold separately, or made into butter; but this is seldom done to any extent. The cows are fed on every kind of food that can increase the milk: brewers' grains and distillers' wash are preferred, when they can be obtained. The grains are kept in large pits, pressed close and covered with earth, under which circumstances they will remain fresh a long time. Turnips and beet-root are used in large quantities; but hay is given sparingly. The cows are generally placed in pairs, with a partition between every two pair. Each cow is fastened to the corner of the stall, where she has a small trough with water before her: thus they cannot gore each other with their horns. The cows chiefly employed in the London dairies are the short-horned breed. The following passage, taken from a work published by Messrs. Blackie of Glasgow ('How to Choose a good Milk Cow'), describes the experience of a London dairyman: "A Yorkshire cow in a London dairy establishment is seldom calculated to give less than twenty quarts of milk daily for the first four months after dropping her calf, and many of their breed have been known to give from thirty to forty quarts daily for a few weeks after calving. In Mr. Biggs' dairy (Edgeware Road), twenty quarts a day is the average quantity of a great proportion of his best cows, and many of them would continue in milk all the year round; but as this would be injurious to the animal, and would diminish the yield in the succeeding year, they are intentionally run dry about six weeks before the time of calving. The whole quantity of milk produced in twelve months by one of these Yorkshire cows cannot be less than 4000 quarts, or 1000 gallons. The retail price is 1*s.* 4*d.* per gallon, and when sold wholesale to the milkman the price realised by the dairyman is not less than 1*s.* per gallon, so that from this datum it appears that a cow giving 1000 gallons per annum produces 50*l.* worth of milk during that period. Of course the feeding is very liberal, and from the high price of green food in the metropolis is necessarily very expensive. The milking and feeding in Mr. Biggs' dairy is as follows:—

4 A.M.	Milked. (A good milker can milk 16 cows in 2¼ hours.)
4 "	1 bushel basket of brewers' grains to every 2 cows.
6 "	3 bushels of swedes or mangold-wurzel to every 2 cows.
7 "	1 truss of hay to every 12 cows.
9 "	Water, which is the only time they are allowed to drink during the 24 hours in winter, and each cow drinks about 24 quarts. In summer water is given twice.
11¾ "	1 bushel of grains to 2 cows.
1 P.M.	Milked again.
2 "	3 bushels of roots to 2 cows.
3 "	1 truss of hay to 8 cows.

In summer the green food consists of clover, rye-grass, or vetches.

The cows are milked twice a day, which occupies about 2¼ hours each time. The cow-houses are cleaned out five times each day, and the gutters kept sweet by allowing water to flow through them. The cows are thoroughly combed and cleaned once a week. From the foregoing data the following calculations of the annual expense of house-feeding a London dairy cow may be deduced—

	£	s.	d.
Winter Food, October 1st to May 1st.			
212 bushels of grains, at 6*d.*	5	0	6
13¼ tons of roots, at 20*s.*	13	5	0
1 ton of hay, at 90*s.*	4	10	0
Summer Food, May 1st to October 1st.			
11½ tons of grass, &c., at 20*s.*	11	10	0
153 bushels of grains, at 6*d.*	3	16	6
Total cost of food	38	2	0
Interest on capital, 16*l.* at 5 per cent.	0	16	0
Annual loss	0	16	0
Attendance	1	5	0
Total cost	£40	19	0
Produce from Cow.			
1000 gallons of milk, at 1*s.*	50	0	0
Calf	1	0	0
Manure	4	0	0
	55	0	0
Deduct expenses	40	19	0
Profit	£14	1	0

In the above calculations no charge is made for rent of premises; but though 1*l.* per cow be struck off for this, the profit is still abundant."

The great dairies about London are kept very clean; but the liquid manure, which would be so valuable for the market-gardens, is lost, and runs off by the sewers. In Belgium the urine would be contracted for at the rate of 2*l.* per cow per annum, which would produce 1200*l.* a year in a dairy of 600 cows, and would pay a good interest for the money expended in constructing large vaulted cisterns under each cow-house.

The dairy farms of England are chiefly in Gloucestershire, Devonshire, and Cheshire. They require a smaller capital than arable farms of the same extent; the chief outlay is the purchase of cows. The rent of good grass land is generally higher than if it were converted to arable land, and the risk from seasons, and the variations in the price of the produce, is much less in a dairy farm than in one where corn is chiefly cultivated. Hence the rents are better paid, and there are fewer failures among the tenants; but the profits of a dairy farm, without any arable land, are not considerable; a decent livelihood for the farmer and his family is all that can be expected. There is no chance of profit in a dairy of which the farmer or his wife are not the immediate managers. The attention required to minute particulars can only be expected in those whose profit depends upon it. The dairies of men of fortune may be arranged on the best and most convenient plan, and be indispensable articles of luxury; but the produce consumed has always cost much more than it could be purchased for. A proper attention to keeping correct accounts of every expense will convince any one of this truth. In a dairy farm the great difficulty is to feed the cows in winter. It is usually so arranged, that the cows shall be dry at the time when food is most scarce, and they are then kept on inferior hay, or straw, if it can be procured. It is a great improvement in a dairy if it has as much arable land attached to it as will employ one plough, especially if the soil be light; but the mode of cultivating this farm must vary from that of other farms, since the food raised for the cows must be a principal object. Corn is a secondary object; and the cultivation of roots and grasses must occupy a great portion of the farm. When the grasses degenerate, a crop or two of corn is taken, and the rotation is chiefly roots, corn, and grass cut for hay, until it wears out. If the roots are well manured, the land keeps in excellent heart. The old pastures are kept for summer feeding. Where there is no arable land near a dairy farm, it deserves mature consideration whether it will be advantageous or not to allow some of the pasture to be ploughed up. It is often a dangerous experiment where the soil is naturally heavy, which is the case with most dairy farms in England. Arable land laid down to grass for the purposes of the dairy seldom produces fine-flavoured butter, or good cheese; but clover-hay is excellent for young stock, or to fatten off the old cows. Lucern is reckoned to make cows give very good milk; nothing however can equal a rich old pasture, as all dairymen agree.

In hiring a dairy farm, it is an object of great importance that the buildings be situated near the centre of the land, and that they be well constructed and convenient. The nature of the feed must be ascertained by experience. It is often impossible to say by mere inspection whether a pasture will make good butter or cheese, especially the latter. But those which have no great reputation may often be highly improved by draining, and also by weeding, a thing too much neglected in pastures.

DAIS, or DEIS, a word which occurs very frequently in old English authors; as in Chaucer, 'Prologue to the Canterbury Tales,' v. 372.

Wel semed eche of hem a fayre burgeis,
To sitten in a gilde halle, on the *deis.*

Tyrwhitt apprehends "that it originally signified the wooden floor (Fr. *d'ais,* Lat. *de assibus*) which was laid at the upper end of the hall, as we still see it in college-halls;" and in most, if not all, of those of the city companies in London, and those belonging to the inns of court. "That part of the room being floored with planks was called the *dais,* the rest being either the bare ground, or, at best, paved with stone; and being raised above the level of the other parts, it was called *the high dais.*" He says that Menage, whose authority has led later antiquaries to interpret *deis* a canopy, has evidently confounded *deis* with *ders.* But *dais* not only signified a canopy in old French, but it is the term still employed in France for the canopy carried over the host in processions, and for that which was formerly, at least on state occasions, held above princes, ambassadors, &c. In the Dictionary of the French Academy, *haut dais* is defined to be the raised place occupied by the sovereign in public ceremonials, whether there is a dais (canopy) above him or not. It is not improbable that as originally applied to the raised platform in a hall, the term was equivalent to—place of the dais—that is, state canopy; the chief seat, which was always placed in the centre of the high board, having a canopy over it. From its central place the principal table itself seems in course of time to have been called the dais, as well as the platform upon which it stood; and people were said to sit *at the dais* instead of *at the table upon the dais:* thus, in Matthew Paris, 'Vit. Ab.,' p. 1070, "Priore prandente ad magnam mensam, quam *dais* vulgariter appellamus." The term is used in this sense by Skelton, Roy, and other writers as late as the time of the Tudors. In royal halls there were more *daises* than one. Christine of Pisa ('Hist. Cha. V.,' p. iii. c. 33) says, that at a dinner which Charles V. of France gave to the emperor Charles IV. in 1377, there were *five daises.* (Ducange, *Glossary;* Tyrwhitt's *Notes on Chaucer's Canterbury Tales,* 4to., Oxford, 1798, vol. ii., p. 403.)

DALAI LAMA. [LAMA; LAMAISM.]

DAMAGES (old French, *damage;* Latin, *damna*), in law, signifies the compensation that is given by the jury (or assessed by the court) to the plaintiff for the wrong the defendant has done to him. That wrong may consist in the non-payment of a debt or the non-performance of a bargain, in which, and similar cases, damages are said to arise *ex contractu,* being given for the breach of the contract or promise to pay the debt or perform the bargain. If the wrong be the infliction of personal injury, or the deprivation of personal liberty, or arise from slander or imputations on personal character, the damages are said to arise *ex delicto;* that is, from the delict or wrong committed by the defendant.

In actions *ex contractu,* where the parties have stipulated for a liquidated sum to be paid as damages, the jury are bound to give the full amount of that sum; but where they have stipulated merely for a penalty to be paid, the jury may give less, or if the parties do not proceed for the penalty, they may give more. If the damages given be excessive, the court will sometimes grant a new trial, but not so if they be too small; at least it is very unusual to do so, except in actions on mere money demands or on inquisitions.

DAMALURIC ACID ($C_{14}H_{12}O_4$). A volatile acid found by Staedeler, along with *damolic acid,* in the urine of the cow. It is an oily liquid, having the odour of valerian, and is heavier than water.

DAMASCENE WORK. The damask, damascene, or Damascus work, so often met with in choice specimens of metal manufacture, especially on the old Damascus sword-blades, is a method of producing a pattern or design by encrusting or inlaying one metal with another. It was introduced into Europe from the Levant, where it was much practised in the middle ages, especially at Damascus. The metals usually employed were silver or gold on copper or iron, gold on silver, or silver on gold; but any other combination would equally come within the principle of the art.

There were several different modes of damascening. If the metal to be damascened were hard, its surface was wrought into fine lines crossing each other, and the designs were afterwards traced upon it; the design marks were filled in with the metal inlay, which was fixed by a strong pressure or by hammering; and the entire work was then burnished, by which the lines uncovered by the incrustation were erased, and a fine polish given to the surface. Another method was that of hatching the incised lines only, and of fixing the incrustation as before. In a third method, when the incrusting metal was of a ductile nature, the pattern was first incised in outline, and the body of the design left on the same level as the rest of the surface; a thin strip of metal was then laid down vertically, and fixed by the insertion of its edges into the exterior incisions; the incrustation was thus in relief, and was afterwards occasionally engraved. A fourth kind of damascene work partook of the nature of *picqué,* or a design formed by small pins or studs, much in vogue in England in the 17th century.

Various European cities had artists who practised damascening; but Venice and Milan were the chief, and the art attained its greatest perfection in the 16th century.

At the Mediæval Exhibition of 1850, and the Manchester Exhibition of 1857, several beautiful specimens of damascene work were collected, including candlesticks, tankards, ink-stands, shields, etuis, swords, &c.; but the most exquisite was Cellini's far-famed shield, presented by Francis I. to Henry VIII., and now the property of her Majesty. It is made of embossed steel, damascened with gold and silver. It has represented upon it, in compartments, scenes from the history of Julius Cæsar, each consisting of numerous figures in relief of the most highly finished execution.

Damascene work is not now much practised in any part of Europe.

DAMASK, a kind of woven cloth, composed both of flax and of silk, which is believed to have been originally brought from Damascus. Linen damask is used for table-cloths and napkins. Until within the last half century, the cloths of this kind used in England were imported from Germany; but the manufacture has since that time been successfully carried on both in Scotland and in Ireland. Damask cloths are of thick texture but fine in quality, and the weaving of them puts into requisition all the skill of the weaver for the production of the elaborate patterns which they bear. Some of these patterns require upwards of twelve hundred changes of the draw-loom for their completion, the method of performing which could not be explained without going into the detail of the art of weaving; it will however be briefly treated in a later article. [WEAVING.] The weaving of silk damask was introduced into England by the Flemish weavers, who fled hither from the persecutions of the Duke of Alva in 1567. For a long time silk damask dresses were used on all occasions of ceremony by ladies of rank and by wealthy commoners; but they were never commonly worn. They were wrought with a great variety of colours, and if the patterns did not exhibit much taste they were sufficiently showy; from the quantity of silk which they contained, they were also very costly. The damask employed at the present day for curtains and the like articles of household furniture is made of a mixture of silk with flax, cotton, or wool; the warp, or long threads, being of the more costly material.

DAMMARA. A resin commonly known as *cowdie-gum.* [DAMMARIC ACID.]

DAMMARIC ACID ($C_{80}H_{30}O_{11},HO$?). A resinous acid found, along with a neutral resin, *dammarane*, in *cowdie-gum*, the product of a large tree of the coniferous species growing in New Zealand. When the cowdie-gum is submitted to distillation it yields two oils lighter than water, to which the names *dammarol* and *dammarone* have been given; they are, however, probably not definite compounds, but mere mixtures of oily hydrocarbons.

DAMMAROL. [DAMMARIC ACID.]

DAMMARONE. [DAMMARIC ACID.]

DAMOLIC ACID. [DAMALURIC ACID.]

DAMP, CHOKE. [MINING.]

DAMPER. There are two or three different modes in which this term is applied to small mechanical contrivances. The damper of a furnace or fire-place is a door or screen which, if drawn partially or wholly across a particular channel, lessens the passage for air, and diminishes the intensity of the heat in the furnace; this damper is therefore a check. As a check, also, does the damper of a pianoforte act; it is a small lever, which presses against a string soon after it begins to vibrate, in order that the vibrations should not continue too long, thereby injuring the completeness and effect of other sounds which are to come after; the damper checks the vibration. There are other pieces of mechanism known in the arts which check a particular action at a particular time, and which are on that account called dampers. A wholly different apparatus is called a damper because it communicates dampness or moisture. When adhesive postage stamps came extensively into use, it was felt by many persons that the method of moistening the liquid gum by licking it with the tongue is both an unsightly and an unpleasant one, and is even injurious to health if often repeated. Hence the invention of damping-machines, or dampers, for moistening the gum of adhesive stamps or labels. Such machines have not come extensively into use, possibly because the requisite simplicity and cheapness have not been attained; but it is an attempt in the right direction, which may meet with ultimate success. Phelp's damper contains a cup or vessel of water, with a pipe extending from thence to a small tray on which a flat piece of sponge is placed, open at the top. Rowland's damper comprises a small vulcanised India-rubber bag or vessel, and a piece of sponge fixed in a holder inserted in the mouth of the bag. Baddeley's damper is an attempt to meet the wants of those who consider that postage stamps ought to be moistened on both sides. Schäfer's and other patented dampers have, in like manner, ingenious appliances for moistening the adhesive composition without the aid of the tongue.

DANCING. [BALLET.]

DANEGELD, sometimes called simply the GELD, was a tax originally imposed, in order, says Thierry ('History of the Norman Conquest'), to maintain a coast-guard against the incursions of the Scandinavian pirates. He adds, that it was this identical fund that was offered to the invaders by way of tribute. The ordinary revenues of the crown were quite inadequate to the expense of either maintaining a force to fight, or to produce the means of bribing their ferocious enemies; and therefore it was found necessary, with the consent of the Wittenagemot, to impose a tax, first of one Saxon shilling, and afterwards of two or more shillings, on every hide of land in the kingdom. In the laws of Edward the Confessor, who abolished the tax, it is spoken of as follows:—De Danegeldo—Danegeldo redditio propter pyratas primitus statuta est. Patriam enim infestantes vastationi ejus pro posse quo insistebant. Ad eorum quidem insolentiam reprimendam statutum est, Danegeldum annuatim reddit; scilicet, 12 denarios ex unaquaque hida totius patriæ, ad conducendos eos qui piratarum irruptioni resistendo obviarent. (Wilkins's 'Leges Anglo-Saxonicæ.') It is known that "in 991 they were bribed and bought off with ten thousand pounds of silver; in 994 with sixteen thousand; in 1001 with twenty-four thousand; in 1007 with thirty-six thousand; and in 1012 with forty-eight thousand. A pound of silver was worth about three pounds of modern money, and would have purchased eight oxen, or fifty sheep." ('Popular Hist. of Eng.,' by C. Knight.) According to the 'Saxon Chronicle' (edit. Gibs., p. 116), this tax was first imposed in 991; it was soon after raised to two and at last to seven shillings on every hide of land, and continued to be levied long after the original occasion of imposing it had ceased.

Whilst the invasions of the Danes were almost annual, our kings derived little profit from this tax, which was all expended in bribing or fighting these invaders; but after the accession of the Danish princes to the throne of England, it became one of the chief branches of the royal revenue. This tax was raised so high, and collected with so much severity by King Canute in 1018, that it amounted to the prodigious sum of 71,000*l.*, besides 11,000*l.* paid by the city of London. ('Chron. Sax.,' ut supr., p. 151.)

Edward the Confessor, who succeeded Hardicnut in 1042, and put a stop to all future payments from the English to the Danes, as well tributary as stipendiary, continued nevertheless to collect danegeld from the subject until the year 1051, when, as Ingulphus and other authors say, he absolutely repealed it. It was revived at an early period of William the Conqueror's reign, and, according to Webb, in his 'Short Account of Danegeld' (4to, Lond. 1756, p. 2), continued to be collected as low as 21 Hen. II., if not later. In the Domesday Survey, danegeld occurs but once by its own name (tom. i., fol. 336 b.), under Stamford, in Lincolnshire. It is mentioned as one of the *Jura regalia* in the Laws of Henry I., chap. 10. Stephen, at his coronation, took an oath that he would remit this tax. (Compare Spelman's and Du Cange's 'Glossaries,' v. 'Danigeldum.')

DANES is the general appellation given to the Scandinavian tribes which in the 9th and 10th centuries became so formidable by their predatory expeditions, and invaded and occupied a great part of Britain and France. The early history of the Scandinavian nations is involved in great obscurity, though Danish and Swedish chroniclers gravely deduce their genealogy from Japhet and his son Gog, and relate their early migration from Asia. But coming to more historical times, there is a poem on the exploits of the Danes in the 3rd and 4th centuries, which refers to their wars among themselves, and in which the Danes, properly so called, or Western Danes, appear as the inhabitants of Jutia, who are also called Scyldingi; while the Sveones (perhaps the same as the Suiones), mentioned by Tacitus ('German') as living near the shores of the Baltic, are called also Eastern Danes, or inhabitants of part of the country now called Sweden. Next to these are mentioned the Geata, or Goths; and in the islands of the Baltic, the Sæ Geata, or Sea Goths, called also Scylfingi. We find also mention of the Northern Danes, probably the Norwegians. ('De Danorum Rebus gestis Seculis III. et IV. Poema Danicum dialecto Anglo-Saxonica ex bibliotheca Cottoniana Musæi Britannici,' edited by G. J. Thorkelin, 4to, 1815.) The common language of all these people was the Norse or Dönsk Tunga, which is still spoken in Iceland. (P. Vidalini, 'De Appellatione Linguæ Septentrionalis, 1775.)

Scandinavian migrations had taken place to North Britain in very remote times; and it appears probable that some of the tribes which inhabited Caledonia in the Roman period had come originally from that quarter. The Jutes and Angli, who, with the Saxons, conquered Britain, came from Jutia, the country of the Western Danes. But after the Saxon conquest, the connection between the migrated tribes and the Danes who had remained in Scandinavia became obliterated, until the end of the 8th century, when the Danes began to make war upon their old kinsmen with all the fierceness of inveterate enemies. Their predatory descents on the coast of Britain became formidable during the reign of Egbert; and under his successors the Danes obtained possession of great part of the island, until Alfred the Great defeated them, and obliged the Danish chieftains to submit. [ALFRED, in BIOG. DIV.] The eastern part of England retained long after the name of Danelagh, or Danish Law, and the population was in great measure of Danish stock, especially to the north of the Humber. After the death of Alfred fresh incursions took place, until, at the beginning of the 11th century, Canute, or Knut, having established himself as sovereign of all the Scandinavian nations, added Britain also by conquest to his sceptre. [CANUTE, in BIOG. DIV.] After Canute's death his successors Harold and Hardicnut held the sway of Britain for a few years longer, after which the line of the Saxon kings was restored in the person of Edward the Confessor. The Norman conquest, which followed close upon the death of the latter, put an end to the Danish invasions on the coasts of Britain. But the Normans themselves were originally of Danish stock in the general sense of the name, having settled in North France under Rollo the Ganger in Alfred's time; and those Norman pilgrims and knights who conquered the kingdoms of Sicily and Apulia in the 11th century were likewise their progeny.

DAPHNINE. Vauquelin first pointed out, in the 'Annales de Chimie,' t. lxxiv., the existence of a peculiar acrid principle in the mezereon (*Daphne Mezereon*). Its properties have been since more particularly examined by Gmelin and Bär. It is prepared by precipitating a decoction of mezereon bark by subacetate of lead, and decomposing the washed precipitate by sulphuretted hydrogen; the solution is then filtered, evaporated, and the residue digested in cold anhydrous alcohol, from which daphnine crystallises.

When it has been purified by washing with cold alcohol, solution in water, and recrystallisation, it forms colourless bitter crystals, which possess neither alkaline nor acid reaction: in cold water they are sparingly soluble, but more so in hot, and also in alcohol and ether. Nitric acid converts it into oxalic acid. It does not appear to have been analysed.

DARIC (Δαρεικός, *Daricus*), a Persian coin of pure gold, stamped on one side with the figure of an archer crowned, and kneeling upon one knee, upon the other with a sort of quadrata incusa, or deep cleft. Harpocration (*in voc.* Δαρεικός) ascribes its origin and name to a Darius of a remote period; but Wesseling ('Observat. Variæ,' 8vo, Traj. ad Rhen., p. 241) and other later writers, upon the authority of Herodotus, give it to Darius Hystaspis, the father of Xerxes, who began his reign B.C. 521. The daric was equivalent in value to the Attic Chrysus (χρυσοῦς), and was worth twenty drachmæ of silver: five darics were consequently equal to an Attic mna of silver (Harpocration). Xenophon, in his 'Cyropædia' (vii.), informs us that the daric was a month's pay for a common soldier. Prideaux ('Connect. of Old and New Test.,' 8vo, Lond. 1725, i. 183) observes, that in those parts of Scripture which were written after the Babylonish captivity (he refers to Chron. xxix. 7, and Ezra viii. 27), these pieces are mentioned by the name of *Adarkonim*; and in the Talmudists (see Buxtorf's 'Lexicon Rabbinicum,' p. 577) by the name of Darkemon, both from the Greek Δαρεικός. It has been suggested, however, that the name is derived from the Persian *daar*, a king, and in that case the daric may have had an origin even earlier than Darius the Mede, and might have been known to the Jews prior to the Captivity. Darics were the gold coins best known in Athens; and when the supply became deficient, imitations of them were made, and hence the existing darics are mostly of Greek manufacture. It would seem extraordinary, when we consider the great number which are recorded to have been employed in presents and bribes alone, exclusive of the purposes of traffic, that so few should have reached modern times, if we did not know that upon the conquest of Persia they were melted down, and re-coined with the type of Alexander. Very few Persian darics are now to be seen in cabinets. There is one in Lord Pembroke's, which weighs 129 grains; and there are three in the cabinets of the British Museum, weighing about 128½ grains each. Mr. Young, the eminent dealer in coins, also possessed two, one weighing about 121½ grains, the other 128¼. The witticism of Agesilaus (Plutarch, 'Apophthegm Lacon.' xl.) is well known, who, being forced to retire from an invasion of the Persian provinces by the bribery used by the great king, said that 30,000 *archers* had defeated him.

The silver coins which go by the name of darics are in truth miscalled. They had no such designation in ancient times. The earliest of them, if we may rely upon Herodotus in a passage already referred to (iv. 166), were struck by Aryandes, the Persian governor of Egypt, in imitation of the darics. "This Aryandes was governor of Egypt, and had been appointed by Cambyses. Some time after, presuming to put himself on an equal footing with Darius, he lost his life in consequence. Hearing by report, and seeing himself, that Darius was desirous to leave some memorial behind him, such as no other king had done, Aryandes followed his example, and met with his reward. Darius took the best gold, and purifying it to the highest degree, struck a coin. Aryandes, being governor of Egypt, did the same in silver; and the silver of Aryandes is now the purest. Darius being informed of what he was doing, put him to death, under the pretence that he was meditating a revolt." The coining of these darics or Aryandics in silver, however, must have been continued after the time of Aryandes. No fewer than eight specimens of this description are in the cabinets of the British Museum. One, formerly Mr. R. P. Knight's, bears the name of Pythagoras, as Mr. Knight conjectured, a king or governor of Cyprus. Others, which have the figure of the archer crowned on one side, have a mounted horseman on the other. They are generally considered as ancient Persian coins, and are commonly, though without any assignable reason, except as bearing the figure of an archer, called darics.

DATA, DATUM. A datum is any quantity, condition, or other mathematical premiss which is given in a particular problem. Thus in the question "to draw a circle which shall have its centre in a given line, and shall touch two other straight lines," the data are as follows: 1, That the figure described is to be a circle; 2, a certain straight line; 3, that the centre of the circle is to be on that straight line; 4, two other straight lines; 5, that the circle is to touch those straight lines. Data may be divided into two classes, the latter class being the restrictions which it is necessary to place upon the class already described in order that the problem may be possible. Thus the preceding problem becomes absurd when the three straight lines are parallel, unless the line on which the centre of the circle is to lie be midway between the two others. Either then the problem must be proposed with the limitation "if it be possible," or an express datum of exclusion must be introduced, namely, that the three straight lines must not be parallel, unless, &c.

In the mere etymology of the word datum all legitimate consequences are data when the premises are data. Thus, given two circles which touch, there are also given two circles which have a common point in the line joining their centres. The book of Euclid known by the name of Data (δεδομένα) is the deduction of magnitudes from other magnitudes, not as to what they are, but as to whether they are determined or not. Thus, one of the propositions is, "If a given magnitude be cut in a given ratio, the segments are given." The preface of Marinus to this book contains a dissertation on the meaning of the term.

DATISCIN. This name appears to have been given to two distinct substances, 1st, to a variety of starch [INULIN]; and, 2nd, to a yellow colouring matter contained in the leaves of the *datisca*.

DATURA STRAMONIUM. [STRAMONIUM.]

DATURINE. [ATROPINE.]

DAUCUS CARO'TA, *Medical Properties of.* The carrot has been sufficiently described. [CARROT; DAUCUS, NAT. HIST. DIV.] For medical purposes the root of the cultivated plant, and the fruit (called improperly *seeds*) of the wild plant, are used. The former rasped down into a fine pulp is sometimes applied raw to chapped nipples, and even cancerous ulcers; but more commonly it is boiled, and beaten into a uniform mass, and applied as a poultice to fetid, sloughing, and other ill-conditioned sores, which it cleanses, and otherwise improves. Upon what its power depends is not well ascertained: the juice of the root, analysed by Wackenroder, gave the following constituents:—

Uncrystallisable sugar, with starch and malic acid .	93·71
Albumen	4·35
Fixed oil (along with some volatile oil) . . .	1·00
Carotin	0·34
Ashes containing alumina, lime and iron . .	0·60
	100·00

A little pectic acid is found.

Carotin is a ruby-coloured substance occurring in four-sided plates. It is tasteless, odourless, insoluble in water, soluble in alcohol, and in ether, more so if fat be present, also in fatty or fixed oils, which it colours yellow.

The volatile oil is colourless, of a peculiar penetrating odour, and disagreeable taste. Thirty-four pounds of the fresh root yield only half a drachm of oil. Probably the oil of the seeds is similar. (Pereira.) The fruits of the wild carrot are about one line and a half long, oval, flat, and clothed along the ridges with hairs. The odour is peculiar, aromatic; the taste aromatic and bitter. Their primary action is warming and carminative; and in their secondary effects, they are occasionally diuretic. They are seldom used. The root of the wild carrot is said to produce injurious effects, and should be avoided.

The cultivated carrot, particularly the yellow kind, contains in the root a large quantity of starch. This is greatest when it is raised on unmanured ground, exactly as wheat when raised on undunged ground has more starch and less gluten than when manured. The quantity in the carrot seems greatest about the end of September. One hundred pounds (troy weight) of the fresh root then yield four and a half ounces of starch. It has been proposed to separate this starch in the same manner as starch from potatoes, to employ it medicinally as a very soothing and demulcent article of food for persons with pulmonary irritation and the cough which remains after the influenza. It is most likely a very digestible form of starch, but not more so than arrow-root. It may be raised at a cheap rate, however, as any light soil will answer, and as no manure is needed it cannot be expensive. The refuse after the starch is extracted is good for cattle, and should not be wasted. The white or Flemish carrot is a valuable food for cattle.

(Rham's *Flemish Farming.*)

DAUPHI'N, the title given to the eldest son of the king of France under the Valois and Bourbon dynasties. The origin of the word has been a matter of some dispute. The Counts of Albon and Grenoble are mentioned first in the 9th century as feudatories of the kingdom of Arles; they afterwards assumed the title of Counts of Vienne, and became independent, like other great feudatories. Guy VIII., Count of Vienne, is said to have been surnamed Le Dauphin, because he wore a dolphin as an emblem on his helmet or shield. The surname remained to his descendants, who were styled Dauphins, and the country which they governed was called Dauphiné. It included the present departments of Isère, Drôme, Hautes Alpes, and Basses Alpes. Humbert II., de la Tour du Pin, the last of the Dauphin dynasty, having lost his only son, gave up his sovereignty by treaty to King Philippe de Valois in 1349, after which he retired to a Dominican convent. (Moreri, and the French historians.) From that time the eldest son of the king of France has been styled Dauphin, in the same manner as the eldest son of the king of England is styled Prince of Wales. Since the dethronement of the elder branch of the

Bourbons in 1830, the title of Dauphin has been disused. The last who bore it was the Duke of Angoulême, son of Charles X.

DAVID'S DAY, ST., March 1. St. David, archbishop of Menevia, now called from him St. David's, in Pembrokeshire, lived in the 5th and 6th centuries of the Christian era; Pits ('De Illustribus Angliæ Scriptoribus') tells us that he died at the age of 146 years. He is said, in the days of the memorable Arthur, to have gained a victory over the Saxons, his soldiers during the conflict, for distinction and as a military colour, wearing *leeks* in their caps. In memory of this fight the Welsh still wear the leek on St. David's Day; and it is to this that Shakspere alludes in 'Henry V.,' act v. sc. 1, when he makes Gower upbraid Pistol for mocking "at an ancient tradition, begun upon an honourable respect, and worn as a memorable trophy of predeceased valour.' (See Brand's 'Popular Antiq.,' edited by Sir H. Ellis, 4to, vol. i.; Brady's 'Clavis Calendaria, 8vo, Lond. 1812, vol. i. p. 228, &c.)

DAY. Any astronomical period which depends directly upon the earth's rotation; or the interval between two transits over the meridian of any point in the heavens, real or imaginary. But the only *days* distinguished by that name in astronomy are the *sidereal day*, the *real solar day*, and the *mean solar day*.

The *sidereal day* is the interval between two transits of the same fixed star; that is, the absolute time of revolution of the earth. It is divided into 24 sidereal hours, &c. It begins when the equinox is on the meridian of the place.

The *real solar day* is the interval between two noons or transits of the sun over the meridian. Owing to the unequal motion of the sun, as well as the obliquity of the ecliptic, it is not of the same length at all periods of the year. The *mean solar day* is the average of all the real solar days; it is derived by supposing a fictitious sun to move round the equator, and uniformly in the same time as the real sun moves from an equinox to the same again. The method of adapting the motion of this fictitious body to that of the real sun will be explained in TIME, EQUATION OF.

The civil day, in England at least, is the mean solar day, and begins at midnight; that is, when the fictitious sun is on the invisible part of the meridian. But the astronomical day always begins at the noon of the civil day, and the hours are reckoned forward up to 24. Thus eleven o'clock in the morning on the twelfth of January (civil reckoning) is 23 hours of the astronomical *eleventh* of January. After noon, and up to midnight, the astronomical and civil reckoning coincide.

The mean solar and sidereal days are thus related: the mean solar day is 24h. 3m. 56·55s., of sidereal time; and the sidereal day is 23h. 56m. 4·09s., of a mean solar day.

The ancients almost universally began their day at sunrise, with the exception of the Arabians, who began at noon, and the Egyptians at midnight. Among the moderns, most of the Eastern nations begin at sunrise, with the exception of the Arabians, who still begin at noon, and the Chinese, who reckon from midnight. The Austrians, Turks, and Italians reckon from sunrise, and other European nations from midnight.

DAYS OF GRACE. [BILL OF EXCHANGE.]

DEACON, an ecclesiastical term of Greek origin, from *Διάκονος* (Diáconus, literally, *a servant*), introduced into the Saxon vocabulary, and continued in use to the present time.

It designates one of the *orders* in the Christian priesthood, the lowest of the three—bishops, priests, and deacons.

The first institution of the order is particularly set forth in the sixth chapter of the Book of Acts. The administration of the charities in the Church of Jerusalem was complained of as partial by the Grecian converts. The apostles, in whom the administration had been vested, thought it expedient to divest themselves of this duty, and to devolve it on other persons, that they might devote themselves to prayer and to the ministry of the word. Seven persons were selected for the office, and by prayer and the imposition of hands ordained deacons.

It appears by the first Epistle of St. Paul to Timothy, that there were deacons in other Christian churches, and probably in all where such an officer was needed. He gives instructions (chap. iii. 8-13) respecting the character which became persons who should be admitted into the office. See also Phil. i. 1. There were also deaconesses in the primitive church, one of whom, Phœbe, is mentioned Rom. xvi. 1. This female officer may be traced to the 11th or 12th century.

The peculiar office of both deacons and deaconesses was to attend to works of mercy, to be the administrators of the alms of the more opulent members of the church.

In the English church the name continues, and the peculiar form of ordination, but the peculiar duties of the office seem to be lost sight of. In fact the Poor Laws, by creating certain civil officers whose duty it is to attend to the necessitous, have rendered the services of the deacon in this his characteristic capacity less necessary.

In some dissenting communities there are deacons who still discharge the duties for which the office was instituted, collecting the alms of the people at the sacrament, and distributing them among the poor. But they are always laymen, or persons who have not gone through the forms, generally few and slight, of ordination, as practised among the dissenters.

There is a form for the ordination of deacons in the English church: some clergymen never take priest's orders. It appears by the Rubric that a person in deacon's orders is empowered to read publicly the Scriptures and homilies, to catechise, to preach when licensed to do so by the bishop, and to assist a priest in divine service, and especially in the Communion. When contemplated in the light in which this form places him, he appears as an assistant to a priest, for he is to seek out the sick and poor and report them to the priest, and in the absence of the priest to baptise. This latter permission has led to the introduction of the performance of other ecclesiastical duties, namely, the celebration of matrimony, and the burial of the dead. In fact, the deacon performs all the ordinary offices of the Christian priesthood, except consecrating the elements at the administration of the Lord's Supper, and pronouncing the absolution.

A person may be ordained deacon at twenty-three. He may then become a chaplain in a private family; he may be curate to a beneficed clergyman, or lecturer in a parish-church, but he cannot hold any benefice, or take any ecclesiastical promotion. For this it is requisite that he take priest's orders.

DEAD OIL. [COAL TAR.]

DEAF AND DUMB, CENSUS OF THE. Till the census of 1851 was taken, the public was without the usual official means of knowing the proportion of the deaf and dumb to the population of the kingdom. No previous account of the people had recognised either the deaf and dumb, or the blind. A statement was made about twenty-five years before, in the annual report of one of the provincial institutions for the deaf and dumb, that the number of deaf mutes in England and Wales alone was not less than 8000, and it was generally received with discredit. In the 'Journal of Education,' No. XIV. (1834), it was stated that actual returns had been procured from various parts of the kingdom, from which it was inferred that the proportion of deaf and dumb persons in South Britain was 1 in 1700; and this data was generally established in the minds of those most interested in the management of the various institutions for this class. The correctness of these estimates was sufficiently confirmed when the registrar-general's report was published. The total number of the deaf and dumb, returned in the various enumerations for the United Kingdom, being—

	No. of Deaf and Dumb.	Population.	Proportion.
England	9,543	16,738,695	1 : 1754
Wales	771	1,188,914	1 : 1542
Scotland	2,155	2,888,742	1 : 1340
Ireland	4,747	6,552,324	1 : 1380
Islands in British Seas .	84	143,126	1 : 1704
Total . . .	17,300	27,511,801	1 : 1590

The above proportions vary in different parts of the kingdom. The county enumerations present some notable facts to which attention will be directed, inasmuch as they not only confirm certain opinions and facts previously known, and thus corroborate the general accuracy of the census returns, but they also point to other facts both new and valuable. The counties of England, Wales, and Scotland, are grouped in twelve geographical divisions:—

I. London, comprises parts of Middlesex, Surrey, and Kent: in the repetition of these counties below, their metropolitan portions are excluded. In London the proportion of deaf and dumb to the population is 1 in 1783.

With this table we may compare the one for France in Departments to the 1st of January, 1853, taken from 'Le Bienfaiteur des Sourds-muets et des Aveugles,' by the Abbé Daras; which is followed by a few extracts from the Abbé's observations on the distribution of the deaf and dumb in France; we shall then review the table of the English counties.

TABLE OF THE PROPORTION OF THE DEAF AND DUMB IN FRANCE.

No.	Departments.	Proportion.	No.	Departments.	Proportion.

The Abbé Daras very properly says, "If a province of France produces on an average one deaf and dumb to 700 individuals; if other districts present only a single case among 2000; and if, again, between these extremes, numerous departments have one in 800, 900, 1000, 1100, 1200, 1300, 1400, 1500, &c., according to their situation, to the south or north of the empire, in a mountainous or flat country, in healthy or unhealthy places, in manufacturing or agricultural districts, &c.; it is evident that this statistical result reveals to families, and even furnishes to the administration, knowledge which may be applied to lessen or extenuate this fearful evil of humanity."

The physical and social aspects of France are thus connected by the Abbé with the facts revealed in the census. "The irregular table-lands which border the frontiers of France on the north, south, and east, and the uncultivated moors which extend on the west to the borders of the ocean, produce the largest number of deaf-mutes. There, on an average, one is found to every 800 inhabitants. The beautiful plains which occupy the centre of the country, on the contrary, contain only one in 1600 inhabitants. The high summits of the Alps, the chain of the Pyrénées, the precipices of the Jura, the flanks of Cevennes, the volcanic soil of Puy-de-Dôme, the rocky Corsica, the rugged regions of Lozère and Cantal, comprehend the provinces most afflicted with deaf-dumbness. There are twenty departments which contain one deaf-mute in 600, in 700, in 800, or in 900 inhabitants, whilst those fertile districts in the interior, which extend themselves by an inclined plain from the western slope of the Alps, of Jura, and of the Vosges towards the Atlantic, contain a much lower proportion; about forty departments exhibit only one deaf-mute in 1300, 1400, 1500, and so on even to 2000 inhabitants.

"With the map of France before us, if we trace to the east the continuous barrier which stretches from the woody Ardennes and the Argonne to the Vosges, and which goes on from the Vosges to the Jura, to the Alps, to the Cevennes, to the Pyrénées, along the frontiers of Baden, Switzerland, Sardinia, the borders of the Mediterranean and Spain, there will be found in Lorraine, Alsace, Franche-Comté, Bresse, Bugey, Dauphiné, Forez, Limagne, Velais, Gévaudan, Vivarais, Rouergue, Rousillon, Bigorre, Béarn, Gascony, rural populations which have lived for ages in the shades of their forests, on the craggy sides of their mountains, or near to the uncultivated borders of their marshy lakes. One can easily imagine that congenital or acquired deafness, and consequent dumbness is multiplied in such localities in a much greater proportion than among those happy populations spread over the rich and salubrious countries of Berri, Touraine, and the Isle of France.

"Having studied this general rule of topographic hygiène in all its applications, we are surprised to find it confirmed where we might expect to meet with an exception. Thus, for example, Provence and Languedoc which separate the Alps from the Cevennes, would appear naturally to produce as many deaf-mutes as the mountains in their vicinity; but no, Provence and Languedoc, being countries with a flat surface and highly cultivated, obey the general rule, and contain fewer unfortunates. It is remarkable that the departments of the Var, Hérault, the Mouths of the Rhône, Aube, Lower Charente, and those watered by the Garonne, only count one deaf-mute on 1500 inhabitants; this ratio applies also to the central level of the country, to the maritime coasts of Brittany, to the valleys of Normandy, to the chalky plains of Champagne, to the hills of Burgundy, and to the river populations of the large streams which flow in the interior. It is not so in the departments covered with thick and old forests, surrounded with mountains, torn with volcanoes, inundated by the waters of lakes, infected by exhalations from marshes. In the first rank of these are Corsica and the Haut-Rhin, which present one deaf and dumb in 600 inhabitants; then come three departments situated on the Alps, the Vosges, and the Pyrenees, which contain one in 700 inhabitants; then come Isère, at the foot of Jura, between the Cevennes and the Alps, Lozère and Puy-de-Dôme, extending along the ridge of the mountains of Auvergne, and lastly Ariège, an escarpment of the Central Pyrénées; in these departments we find one deaf-mute in 800 inhabitants.

"The departments which are about to follow are under similar conditions of climate, temperature, and topographic hygiène; they are Gard, at the foot of the Cevennes, which has one deaf-mute in 910 inhabitants; Cantal, covered with a population thrown on the granite soil of High Auvergne, counting one deaf-mute in 917 inhabitants; the Lower Alps, shaded by Mount Viso and the neck of Argentière, and constantly exposed to unhealthy cold and damp winds, producing one deaf-mute in 927 inhabitants; the Eastern Pyrénées, overlooked by the high summits of the neck of Perche, the neck of Arras, and the neck of Pertuis, showing one deaf and dumb in 928 inhabitants; and, lastly, the Landes and the Jura, evidently subjected by the nature of the soil and the topographical character to the same morbid vicissitudes, and giving one deaf and dumb respectively to 946 and 976 inhabitants."

The Abbé calls the attention of all who are interested by duty or by their avocations to the observation of these phenomena; he considers that natural consequences may be deduced from the facts he has accumulated, and the observations which he has made, which may tend to shed light on one of the most insolvable and mysterious problems of general hygiène. The average number of deaf-mutes in France is high compared with other countries, and with the proportion assigned to Europe, namely, in France 1 in 1212; in Europe 1 in 1585. In France, as elsewhere, there are social causes at work, producing both congenital and acquired deafness, such as the influence of hereditary predispositions, the intermarriage of blood-relations, the secluded habits of certain communities, and other conditions of life, the moral and physical temperaments, and ignorance of the nature and consequence of certain diseases; and to these, as well as to climate, situation, soil, atmosphere, and other topographical influences, a large proportion of the deaf-dumbness so prevalent must be attributed; at the same time there are anomalies in France as elsewhere, which for the present defy all efforts towards their solution.

It is not possible to give such apparently plausible reasons for the greater or less prevalence of deafness in the different counties of England, as the extracts above give with reference to the various departments of France, yet there are some notabilities, as well as some anomalies, which it seems desirable to place on record. Taking the two counties in which deafness appears most to prevail, Herefordshire with 1 in 1054, Worcestershire with 1 in 1160; it appears at first sight that these two counties are among the healthiest in England, both bring to the mind hop-yards, orchards, and fertile lands, watered with fine rivers. Herefordshire, though not mountainous as a whole, is almost hemmed in by high lands; on the north by those of Shropshire, on the west by the Black Mountains and those of Radnorshire, on the east by the Malvern Hills and the Forest of Dean; Worcestershire is almost similarly enclosed, having the Clent and the Lickey Hills on the east, and the Malvern and Abberley Hills on the west; some of these hills are however considered the most healthy districts in England. It is not surprising to find Derbyshire and Cornwall respectively with 1 in 1272 and 1 in 1278 inhabitants deaf and dumb. Both experience and tradition point to mineral districts and exposed maritime coasts as unwholesome to the constant dwellers there. Derbyshire has long been known as a county in which goitre prevails, and glandular swellings, arising from struma, are often the cause of deafness. Cornwall, though mild in climate, is exposed to the heavy clouds from the Atlantic, surcharged with moisture, which being condensed by the high lands in the centre of the county, pour forth torrents of rain. The prevalent moisture in this case may be favourable to conditions which produce congenital or acquired deafness. The next group of counties, with their proportions of deafness varying from 1 in 1406 of the inhabitants to 1 in 1493, are Dorsetshire, Devonshire, South Wales, Wiltshire, Somersetshire, Essex, and Shropshire; all these are maritime districts except the last; the mere vicinity of the sea in these fine climates of the south of England cannot surely be favourable to the production of deafness, and we must look for some other cause for the mysterious visitation. Shall we look for it in social causes? There is much struma on the coast, but it often arises from the poverty of the population—irregular work and wages—unequal and often poor feeding—exposure to weather—and bad dwellings without due means of ventilation; these observations apply to most of the fishing-towns in all parts of the kingdom. We next come to North Wales and Gloucestershire, with respectively 1 in 1514 and 1 in 1565 of their population deaf-mutes; the districts are very dissimilar in their physical features as well as in their geographical position; the same cause for deafness can scarcely have struck them both. The next group of counties with a proportion of from 1 in 1614 to 1 in 1674, includes Buckinghamshire, Westmoreland, the West Riding of Yorkshire, Sussex, and Berkshire. Westmoreland, with its lofty mountains and barren moors, has then to sympathise with the pleasant and fertile vales of Buckingham, and the manufacturing industry of West Yorkshire with the downs of Sussex: truly the physical characteristics here are too conflicting to account for the striking similarity in these proportions. In the next gradation, namely, from 1 in 1714 to 1754, are the counties of Rutland, Suffolk, Bedford, the North Riding of Yorkshire, and Norfolk; all these are agricultural counties, and on the eastern side of the country, but there seems no reason for their greater degree of exemption from deaf-muteism than some that have been previously named. Northumberland, Northamptonshire, Cambridgeshire, Staffordshire, Lincolnshire, Hertfordshire, and Cheshire present proportions varying from 1 in 1818 to 1 in 1874, but with no apparent reason why Lincolnshire on the east, Cheshire on the west, and Northumberland on the north, should produce such similar results. The counties which contain respectively 1 in 1917, 1 in 1947, and 1 in 1958, are Cumberland, Surrey, and Leicestershire; so that Cumberland, on the Solway, is more favoured than its nearest neighbour Westmoreland, notwithstanding its greater proximity to the sea; and Leicestershire and Surrey, both inland, populous, manufacturing, and highly cultivated, have no immunity from these causes. Hampshire, Warwickshire, Oxfordshire, Lancashire, and Nottinghamshire vary in their proportions from 1 deaf-mute in 2000 to 1 in 2088; the same dissimilarity in position, and in the occupations of the people prevails here as in some of the results we have previously considered, with this notable exception, that three of these counties have large manufacturing populations, and confirm to some extent the truth of the registrar-general's observation, that "a greater degree of prevalency of deaf-dumbness seems to exist in rural and hilly localities than amidst urban and manufacturing populations." The last group of counties, showing a variation of from 1 in 2215 to 1 in 2488, comprises Middlesex, the East Riding of Yorkshire, Monmouthshire, Kent, and Durham. Here are placed together dense and sparse populations, mountainous and flat districts, and one mining county. Can anything be more dissimilar? Yet these counties are more exempt from deaf-dumbness than any other part of England, save Huntingdonshire! a small county with a rural population, and with one-fifth of its acreage fen-land. If marshy districts were productive of deafness, Huntingdonshire, Cambridgeshire, and some portions of Norfolk and Lincolnshire, should have this unfortunate pre-eminence; but if the enumerators of the Census are correct, these counties suffer less in this respect than many others, and we are instructed to seek other causes for the prevalence of the infirmity.

We do not totally reject the theory of the Abbé Daras; to a limited extent we are able to confirm it; but we are assured that topographic statistics will not enlighten us generally on the mysterious causes of deafness. We look to medical statistics and to the economy of social life to alleviate some of the evils we have been considering. That there is some connection between the physical character of a country or district and deafness there can be no doubt. In some cantons of Switzerland one deaf-mute is found in 200 inhabitants; Norway and Sardinia again present us with large proportions; and in our own country, the mountainous districts of Scotland and the Penine chain of hills produce analogous results; the plains of England, on the other hand, with a few remarkable exceptions, generally exhibit the smallest proportion of the deaf and dumb; and so it is with the plains of Luxembourg and Würtemberg, and the kingdoms of Tuscany, Bavaria, Belgium, and Holland. In Ireland, as in England, the deaf-mute is found most in the rural and least in the civic districts; the flat counties, such as Roscommon, Westmeath, Dublin, and Kildare, show the fewest cases (1 in 1935), while mountainous Wicklow has 1 in 1031, and Mayo, Limerick, Donegal, Waterford, and also Tipperary, Tyrone, and Fermanagh, the former on the coast, and all presenting mountain ranges, show an average of 1 in 1068.

Confirmatory of these views, we can with confidence adduce the following particulars: a very large majority of the pupils who have been admitted into the Yorkshire Institution have been from the district of the West, traversed by the great Penine chain. This chain commences in the Staffordshire moorlands, goes through Derbyshire (the Peak), thence into Yorkshire (Stanedge and Blackstone edge), and extends irregularly northwards (Ingleborough, Wharnside) to the Cumbrian mountains. On the east of this chain of hills, in Yorkshire, and within a few miles of them, are the large towns of Sheffield, Rotherham, Barnsley, Holmfirth, Huddersfield, Halifax, Dewsbury, Bradford, Leeds, Wakefield, Keighley, Skipton, and Settle. This mountainous district, with its towns, has supplied the Institution with 300 out of its 534 pupils; the plain of York with 35, that of Selby with 13, of Doncaster with 32, the North Riding with 37, Hull and the East Riding with 33, and the remaining number have been from localities less definitely characterised. It is true that the dense population of Yorkshire is found in the towns above alluded to, but we have already seen, and the observation has been repeatedly confirmed, that the proportion is much less in towns than in agricultural and hilly districts. A very few years ago the writer of this article visited one of the new rising towns within the influence of this range of hills, for the purpose of inquiring into several cases of deaf and dumb children resident there. He was taken into house after house, and found that he was among a wide circle of relations. At length he made the observation, that many intermarriages seemed to have occurred in the different families, and received this ominous reply: "We're all related here." "No wonder, then," he answered, "at the prevalence of deafness." And this was not a mere guess at the cause of the malady, but was the result of long-continued observation. In addition to the physical conformation or position of a district or country, the seclusion of mountainous localities is unfavourable to social developments; those who are shut out of the world by natural circumstances, or from other causes, are driven to each other for companionship and for nearer ties, and to a certain extent this may account for the prevalence of the deaf and dumb in the cantons of Berne and Argovie, in Switzerland; in Norway; in Sardinia; in Corsica, Haut-Rhin, Isère, Lozère, Cantal, and other mountainous and secluded departments in France; and also to some extent in the remote agricultural districts of our own kingdom.

America furnishes us with the following table from the census of 1850. There are other tables to which we have access, but we select this to illustrate a special point:—

Colour.	Population.	No. of Deaf and Dumb.	Proportion.
Whites . . .	19,553,068	9136	1 in 2073
Free coloured . . .	434,495	136	,, 2956
Slaves	3,204,089	531	,, 6221

It appears that among the free coloured population 1 in 2956 is deaf and dumb; among the slaves only 1 in 6221. An American writer says, "In *every state north* of the Potomac and Ohio, the proportion of deaf and dumb among the coloured population is much greater than in *any state south* of those rivers, and in the aggregate of the two sections almost four times as great in the northern as in the southern states. It is also to be observed that in the northern states the proportion of deaf and dumb is generally much greater among the coloured than among the white population, whereas in all the southern states the case is precisely the reverse; the coloured population of the south it is well known are chiefly slaves, whereas at the north they are mostly free. If, then, the census has been correctly taken in both sections, we are led to conclude that deafness is frequently occasioned by the want of physical comforts, with which it is well known the slaves of the south are, as a body, much better provided than the free blacks of the north." The above paragraph was written twenty-five years ago, and referred to the American census of 1830; succeeding enumerations perpetuate similar proportions to those alluded to, and the observations are fully applicable to the census of 1850. This, however, is not a satisfactory mode of accounting for the greater prevalency of deafness among the coloured free population, as compared with the white race. The free coloured population of the north are far removed from the genial climate of their race, while the slave populations of the southern states are in the enjoyment of a climate adapted to their nature, and this is a more probable solution of the difficulty than that which attributes the freedom from deafness among the slaves to their possession of more bodily comforts than fall to the lot of the free coloured population of the northern states; besides, there are more deaf and dumb proportionately among the whites in the southern than in the northern states; these whites, chiefly planters and their agents, are in no want of bodily comforts, and it may fairly be inferrred, that the high temperature which is favourable to the slave population of the south is pernicious to the white race, whether European or Anglo-American. Warm countries and plains, as Tuscany and Luxembourg, appear to contain a smaller proportion of the deaf and dumb than cold and mountainous ones. Change of climate has doubtless an influence in promoting a tendency to certain diseases in a new generation, and probably to some of those productive of deafness; but this result will only follow where the transition is violent, as from a cold or temperate to a hot climate, and the reverse. *To secure the highest conditions of health, every race should therefore confine itself to its own natural latitudes.*

The report of the Irish commissioners on the "Status of Disease" must be considered as one of the most valuable contributions that has ever been produced on those infirmities to which humanity is subject; such a report for the United Kingdom, when the census is again taken, would be invaluable to all institutions established for the alleviation of permanent maladies; and much assistance might be obtained from the officers of such institutions if they were previously apprised of the nature of the inquiries to be made. The science of statistics has still much to do for the deaf and dumb, but the inferences from topographical causes must always be faulty in accounting for the prevalence of the malady. Mention has been made of some anomalies which they cannot explain; they cannot account for the discrepancies between the neighbouring counties of Monmouth and Hereford, between Huntingdonshire and Worcestershire; they cannot show why the healthier province of Denmark, the island of Bornholm, should have more than double the proportion of deaf and dumb that are found in Laaland and Falster, which are considered the unhealthiest parts of the kingdom; nor why, generally, there are proportionably fewer deaf and dumb to be found in towns than in those resorts of health which citizens usually seek for their salubriousness, namely, the sea-coasts, the rural, and the mountainous districts. Some additional light will be thrown on this part of the subject in the article Deaf and Dumb, Vital Statistics of, and some of the causes which produce and perpetuate deafness, independent of climate and locality, will therein be considered.

The following table is drawn from the census returns for 1851, reference being made to the pages in which detailed information will be found respecting each county; the portion referring to Ireland is taken from the report of the commissioners; special attention will be directed to a few points in it, chiefly in the words of the registrar-general:—

Number and Ages of Males and Females returned as Deaf and Dumb.

Registration Counties.	All Ages.		Under 5 Years.	5–	10–	15–	20–	25–	30–	35–	40–	45–	50–	55–	60–	65 –	70–	75–	80–	85–	90–	95–	100 and upwards.	Reference to Census of Great Britain.
	Both Sexes.	Males and Females.

	17,300	Total Great Britain and Ireland.																						

The aggregate number of the deaf and dumb would be increased by a considerable addition to the column "under 5 years," but for the difficulty of ascertaining the existence of deafness, and consequent dumbness, in the early years of life, and the natural indisposition of parents to form a painful conclusion on the subject while the slightest grounds for doubt exist. A rough estimate of the omissions from this cause may be made by assuming the deaf mutes under 5 years of age to bear the same proportion to the general population of the same age as the deaf and dumb aged 5 years and upwards bear to the residue of the population. Under this assumption, the number returned under 5 years would be 1801 deaf mutes, instead of 560. In Ireland it is assumed on similar grounds that the number returned under the first quinquennial period should be 492 instead of 227. Under this hypothesis the proportion of deaf and dumb in the United Kingdom would be increased from 1:1590 to 1:1460.

In Great Britain the greatest number was returned between the ages of 5 and 15, then between 15 and 30; after 50 there is a very sensible diminution, showing that the deaf and dumb are not, like the blind, long-lived. In Ireland the greatest number was returned between the ages of 15 and 30, with a similar diminution after 50. Of the 21,487 blind persons in Great Britain, only 2929, or less than 14 per cent., are under 20 years of age, a circumstance tending to show that cases of blindness at birth are not very common; while 10,102 persons, or 47 per cent., are at the advanced ages above 60. These facts lead to the conclusion that blindness in many cases may have arisen as a natural infirmity of old age, and also show the great longevity of the blind, notwithstanding the accidents to which they are liable. Of the 12,553 deaf mutes in Great Britain, only 783, or 6¼ per cent., had reached 60 years of age, a fact showing the unfavourable position of this class as regards length of life; while those under 20 years of age, although the numbers are unquestionably deficient, amounted to 47 per cent.

The following table is taken from the thirty-fifth annual report of the New York Institution for the Deaf and Dumb, with some additions and corrections of a later date than the original document; the whole would be more satisfactory if we could in all instances quote from information of more recent dates:—

NUMBERS AND PROPORTIONS OF DEAF AND DUMB IN EUROPE AND AMERICA.

COUNTRIES.		Date of Enumeration.	Deaf and Dumb.			Population.	Proportion of Deaf and Dumb.

DEAF AND DUMB, VITAL STATISTICS OF. The subject of deafness and its consequences has of late received a considerable degree of attention, but assuredly not more than its importance deserves. As one result, there is a somewhat general acquaintance with the fact that deafness prevails widely, but comparatively few, excepting those brought professionally or by relationship into daily contact with individuals so conditioned, form anything like adequate notions of the amount of deprivation under which a totally deaf person labours. Till institutions for the instruction of the deaf and dumb began to multiply, and thus to attract public notice and sympathy towards this unfortunate class of persons, it was believed that the deaf and dumb formed an inconceivably small proportion of the population; but the last census has dissipated this erroneous belief, and shown the public that there are within the limits of these islands 17,300 deaf and dumb persons. [DEAF AND DUMB, CENSUS OF THE.] Perhaps one cause of the general want of knowledge on this subject is the incapability of the deaf and dumb to give utterance to their own deficiencies; the very nature of their deprivation prevents their making it known and obtaining relief: thus generations have lived and died in wretchedness and obscurity.

Deafness occurs in every degree, in some cases only amounting to an insensibility to very sharp notes. Many people cannot hear the squeaking of the bat and the mouse. By holding the nose, inflating the ears, and ceasing to breathe, the ear is rendered more open to base notes, and more deaf than it naturally is to sharp notes. Dr. Wollaston constructed a small organ, whose notes began where the sharp notes of ordinary instruments end; the notes of his organ increased in sharpness till they became inaudible, though he was certain that it continued to give sound from feeling the vibrations equally with the lower notes. He thus found that some people could hear seven or eight notes higher than others, and that children could generally hear two or three notes higher than grown-up people. In some persons the accuracy of the ear is merely impaired in distinguishing faint sounds, and sounds somewhat similar; instances of this kind are particularly evident in infants, whose first attempts at speech are a very remote similarity to the sounds they hear, and become more perfect as their ear is educated, and in some cases remain imperfect through life, in consequence of defect in the organs of hearing. All imperfections of speech do not arise from imperfect hearing: an indistinct articulation may result from various other causes, from carelessness, from defective organs of speech or an imperfect formation of those organs, from irregular respiration producing hesitation, and in some instances proceeding from nervousness. The principles which regulate utterance have been practically considered and acted upon by many professors who successfully practise the cure of stammering. The discovery of these principles is due to Dr. Arnott, whose work, 'Elements of Physics,' should be consulted by all those persons who wish to ascertain the causes, moral or physical, which tend to produce defective speech. [STAMMERING.]

By total deafness is meant that state in which the organs of hearing are as insensible to sound as any other part of the body. To persons in this condition sound is a mere vibration, which can be felt, but very imperfectly distinguished. Yet persons who are generally considered as totally deaf, are not all equally so. There are cases where the firing of a gun is unheard though immediately near the deaf person, and others where a gun fired at a quarter of a mile distant is heard, and distinguished from the falling of a heavy weight upon a boarded floor. In some instances, the human voice in a great variety of its louder single intonations can be recognised, though the loudest reading or the highest pitch of a speaker would make no impression. The late Dr. Itard, of the Imperial Institution for the Deaf and Dumb at Paris, considered that more than half of the pupils received into that institution are of that class who hear the least; about the same proportion would be found in the English institutions. The other half comprise cases more or less of imperfect deafness, an expression which must by no means be confounded with imperfect hearing. Mr. Toynbee, the aural surgeon to the Asylum for the Deaf and Dumb, in Kent Road, London, gives as the result of an examination of 411 children in that asylum, that 245, or three-fifths, were quite deaf, while 166, or two-fifths, heard certain sounds. In all these conditions of deafness, the person is consequently *mute*, or *dumb*. Hence the expression *deaf mute*, as used in the Continental languages, and *deaf and dumb*, as used in England and America, to designate a person so deaf as to be inaccessible by the ordinary means of lingual communication, and unable to make known his thoughts, wishes, and feelings, in our conventional tongues. As natural articulation can only be acquired by those who hear, it follows that, according to the condition of the power of hearing will be, *cæteris paribus*, the distinctness of articulated sounds. Hence, in the instruction of deaf-mutes in artificial articulation, it is generally found that those pupils who can in some degree distinguish the different tones of the human voice become the best speakers. There are certainly cases where the articulation of a totally deaf person is pleasanter to hear, softer, and less monotonous, than in some instances of imperfect deafness; but these depend upon other causes, as the natural tone of the voice, the attention of the pupil, or the care of the instructor.

When the term deafness is used in this article, it is intended to convey the idea of an absence of hearing power so total as to exclude the reception of sounds producing ordinary vibrations. Persons in this state are shut out from the usual means of converse and communication with the world; they *feel* concussions, and also vibrations, which are in direct contact with some portion of their body; but they are deaf to the loudest conversations and to all the ordinary means of direct intercourse by the living voice, as well as to the thousand charms which delight the sense of hearing: there are several degrees of this kind of deafness. Difficulty of hearing is another thing, and may be partial or temporary. It is often a concomitant of age, of local disease, or of general functional derangement. In this case the sense is only impaired; in the other it either has not existed or has been destroyed. There is a wide difference between a diminished sense of hearing and a total want of the power. Should the case be one of deafness from birth, it is called *congenital*; should the power of hearing have been lost from the supervention of some disease in the infancy of life, it may yet be as total as if from birth, but it is then a case of *acquired* deafness. In either case it is accompanied with dumbness; for those who have never heard sounds cannot imitate them, and those who become deaf before they have heard spoken words are in the same condition,—dumb. Such children are prevented from exercising that instinctive faculty of imitating sounds and speech, which constitutes one of the main pleasures and one of the most improving exercises of childhood. Again, deafness may come on at a much later period, and utterance thenceforward begins to be thick, guttural, and indistinct, so as to be frequently misunderstood; the deaf person then takes less pleasure in exercising a faculty which he finds so comparatively useless, and he becomes dumb more from choice than from necessity. This, however, is not the invariable result, but depends to some extent on temperament. Thus it was with Dr. Kitto, who gives this account of himself in his little volume 'The Lost Senses:' "Before my fall my enunciation was remarkably clear and distinct; but after that event it was found that I had not only become deaf, but spoke with pain and difficulty, and in a voice so greatly altered as to be not easily understood. I have no present recollection of having ever experienced positive pain in the act of speaking; but I was informed by one who was present, and deeply interested in all which took place at that time, that I complained of pain in speaking; and I am farther told, that my voice had become *very similar to that of one born deaf and dumb, but who has* *been taught to speak*. . . . . Although I have no recollection of physical pain in the act of speaking, I felt the strongest possible indisposition to use my vocal organs. I seemed to labour under a moral disability which cannot be described by comparison with any disinclination which the reader can be supposed to have experienced. The disinclination which one feels to leave his warm bed on a frosty morning is nothing to that which I experienced against any exercise of the organs of speech. The force of this tendency to dumbness was so great, that for many years I habitually expressed myself to others in writing, even when not more than a few words were necessary; and when this mode of intercourse could not be used, I avoided occasions of speech, or heaved up a few monosyllables, or expressed my wish by a slight motion or gesture."

When Kitto was voyaging to the Mediterranean, his kind-hearted and intelligent companions had recourse to a very justifiable artifice to induce him to use his vocal powers. His account of it, and its results, show what may be accomplished in cases of unwillingness to speak on the part of the deaf, who have once acquired the knowledge of language and the power of speech. "After much reasoning with me on the matter, they entered into a conspiracy, in which the captain of the ship joined, not to understand a word I said, otherwise than orally, throughout the voyage. In this they persevered to a marvel; but as I had much to ask, since I had not before been at sea, I made very great progress with my tongue during the six weeks' voyage, and by the time we reached our destination had almost overcome the habit of clutching a pen or pencil to answer every question that was asked me. From this time I usually expressed myself orally to those whom I knew, in the ordinary intercourse of life; but when my communication required many words, it was usually conveyed in writing. This, also, I at length dropped, and strangers only were addressed in writing. Finally, I ventured to accost even strangers with the tongue, and it was only when not understood that I resorted to the pen. At first, strangers could rarely understand me without much difficulty; but under the improvement which practice gave, my voice was so much bettered that the instances in which it was not readily understood gradually diminished, and at the present day I rarely find even a foreigner to whom my language is not clear."

The importance of inquiries into the causes of deafness has been recognised in all our institutions for the deaf and dumb, and ought to be urged upon the registrar-general when the next census for Great Britain is taken. The report on the 'Status of Disease' in Ireland has to a certain extent cleared the way and shown the value of such inquiries. The series of questions issued by the commissioners in that country is given below, and might be adopted in future investigations. They show the data on which the tables in the report were constructed. They were kindly received by the community, and in only one instance was the required information refused.

1. Whether the person was born deaf and dumb, or became so afterwards.

2. If he (or she) was born deaf and dumb, to what cause is such defect attributed by the friends or relatives; whether to fright, hereditary predisposition, or the near relationship of parents—such as the intermarriage of cousins? If attributed to any of these causes, state the degree of relationship existing between the parents, and specify the nature of the fright or accident experienced.

3. If he (or she) became deaf and dumb since birth; state at what age, and to what cause or disease has such been attributed.

4. Is he (or she) paralytic, idiotic, or in any other way mentally or physically affected?

5. Whether any other members of the family, parent or parents, or grandparents, uncles, aunts, or cousins, have been deaf and dumb, and whether they were by the father's or the mother's side. If such relatives were living on March 30, 1851, please state their names, and the barony, parish, and townland in which they were then residing.

6. Whether other members of the family, either dead or absent, such as brothers or sisters, were affected with deaf and dumbness; and if so, state the number and the position of each in the family, such as first, second, or third child, &c. If they were alive upon March 30, 1851, state where they lived: and if dead, give the date and cause of death, and the age at which they died.

7. If the person is educated, state where, and by what means such education was acquired.

8. State ——'s position in the family, whether first, second, or third child in a family of living, and dead. N.B.—State the number of living and dead required in this query.

9. If he (or she) has been married, state the result of such marriage in males and females, and whether any of them have been mute from birth, or became so by accident or disease.

The efforts made by our institutions, those of different countries of Europe, and in some instances by their governments, and by America, have from time to time thrown considerable light on the causes of deafness; but, except the Report for Ireland above referred to, nothing of importance or authority has yet been published in this kingdom; the medical and social aspects of deaf-dumbness have therefore been very partially considered. It is proposed in the present article to bring together such tables and facts as are trustworthy, and available for the purposes of comparison, together with a body of statistics which have recently been collected for the same object.

TABLE I.

PROPORTIONS OF CONGENITAL AND ACQUIRED DEAFNESS. (UNITED KINGDOM.)

	Cases.	Congenital.	Acquired.	Uncertain.
In London Asylums (Toynbee) . . .	411	313	98	
Glasgow Institution to 1855 . . .	440	351	89	
Yorkshire ditto 1859 . . .	534	378	141	15
Birmingham ditto 1859 . . .	412	319	93	
Liverpool ditto 1859 . . .	305	209	79	17
Newcastle-on-Tyne ditto 1859 . . .	155	103	52	
Belfast ditto 1859 . . .	316	273	43	
Exeter ditto 1859 . . .	239	183	56	
	2812	2129	651	32

The discrepancies in this table are not greater than might be expected, some of them may arise from imperfect knowledge on the part of those who furnished the information, but it is highly probable that if there are errors in one column they are balanced by opposite ones, and we may come to the very safe conclusion that *three-fourths* of the aggregate cases which are brought to our institutions are of congenital deafness. This is the largest number of cases that has ever been accumulated for comparison, connected with the institutions for the deaf and dumb in this kingdom.

The report on the status of disease for Ireland presents a very different proportion, which cannot be reconciled with the result obtained in any other country. It gives us a total of 4747 (excluding the dumb not deaf, the paralytic, and the idiotic); of this number 3885 were born deaf, and 535 only became so after birth; 327 cases are, however, reported as uncertain or unknown; still if these were added to the cases of acquired deafness, the proportion would remain very large of congenital cases. The Belfast institution proportions, in Table I., are to a considerable extent confirmatory of the large number of congenital cases in Ireland.

TABLE II.

PROPORTIONS OF CONGENITAL AND ACQUIRED DEAFNESS. (UNITED STATES.)

	Cases.	Congenital.	Acquired.	Uncertain.
Hartford Institution to May, 1851 . .	1060	537	463	60
New York ditto to January, 1854 . . .	1148	492	431	225
Ohio ditto to December, 1854 . . .	581	215	281	85
Kentucky ditto 1849 to 1851 . . .	85	44	32	9
Indiana ditto 1849 to 1851 . . .	195	104	82	9
Illinois ditto to January, 1851 . . .	95	44	48	3
Tennessee ditto 1849	31	19	8	4
Philadelphia ditto to January, 1853 . .	703	376	251	76
	3898	1831	1591	476
Deduct for repetitions, pupils of more than one school	22	13	8	1
	3876	1818	1583	475

This table shows that more than *two-fifths* of the cases are of acquired deafness, leaving out of consideration the uncertain ones. Three-fourths of the English pupils and not quite one-half of the American ones were born deaf and dumb. One-fourth of the English pupils and two-fifths of those of the United States became deaf by accident or disease. The European table which follows (excepting Germany) offers somewhat similar results to that for Great Britain, namely one-fourth acquired to three-fourths congenital.

TABLE III. PROPORTIONS OF CONGENITAL DEAFNESS. (EUROPE.)

	Cases.	Congenital.	Acquired.	Uncertain.
Belgium, 1835	1891	1484	407	
Duchy of Modena, 1838	353	267	86	
Tuscany, 1843 (*including uncertain) .	697	*432	265	
Groningen Institution (Holland), 1843 . .	594	409	185	
Paris ditto (France), 1829 to 1836 . .	238	171	67	
Nancy ditto (France), 1828 to 1850 . .	300	233	67	
Copenhagen ditto (Denmark), before 1856 .	88	54	34

United Kingdom, from Table I. . . .	2812	2129	651	32
	7137	5310	1795	32
Ireland Census, 1851	4747	3885	535	327
European Returns, except Germany . .	11884	9195	2330	359

TABLE IV.

PROPORTIONS OF CONGENITAL AND ACQUIRED DEAFNESS. (GERMANY.)

	Cases.	Congenital.	Acquired.
Institution of Hamburg, to 1847	57	31	26
„ „ Leipsic, to 1828	123	54	69
„ „ Dresden to 1828	38	27	11
„ „ Munich, 1804 to 1835	135	79	56
„ „ Pforzheim, 1833	62	19	43
„ „ Prague, 1826	165	77	88
„ „ Cologne, 1850	85	33	52
Total of German Schools	665	320	345

Hence it appears that in Germany more than half of the cases reported, namely, 52 per cent., were of acquired deafness, an extraordinary revelation if this result may be taken to represent the proportions throughout the deaf and dumb population of that country, and one that should lead to further investigations. As a country, the United States approximates more nearly to Germany than any other, showing an average of 42 per cent. of acquired deafness, thus:—Ohio nearly 51 per cent., Illinois 45, Hartford 44, Indiana 42, Kentucky 40, New York 38, and Philadelphia 36 per cent. These proportions are for the different districts whence the respective institutions are supplied with pupils.

This great prevalence of acquired deafness in Germany and the United States may now be usefully compared with the proportions in the United Kingdom, and with other parts of Europe. Ireland, the country *par excellence* of the congenitally deaf, presents us with only 11 per cent. of acquired deafness, and with 82 per cent. congenital, the other 7 per cent. being of uncertain origin. The four northern counties of England, represented by Newcastle-upon-Tyne, show a proportion of 33 per cent. of the pupils of acquired deafness; Liverpool, representing portions of Lancashire, Cheshire, and a large floating population from various places, exhibits 26 per cent. of its cases of acquired deafness; the Yorkshire Institution, operating chiefly within that county, has also had 26 per cent. of its cases of this class, and 3 per cent. uncertain; London and Exeter show an equal ratio, namely, 24 per cent.; the former not only provides for the metropolis, but also receives pupils from all parts of the kingdom, while Exeter is limited to the four western counties; Birmingham receives children from the midland counties chiefly, and shows that 22 per cent. of them were not born deaf. Glasgow obtains about half its pupils from Lanarkshire, and the others from all parts of Scotland, and shows that 20 per cent. of its number were not congenitally deaf, while Belfast differs but little from the Commissioners' Report for Ireland, by witnessing that only 14 per cent. of its pupils became deaf after birth.

We are thus made aware that the average of acquired deafness in Great Britain is 25 per cent., while Germany has more than double that proportion, and the United States of America show a ratio of 42 per cent. The average for Europe, excepting Ireland and Germany, is the same as for Great Britain, but offers the following anomalies: Belgium, St. Petersburg, the Duchy of Saxe-Altenburg and Nancy (France) vary from 20 to 22 per cent. only; the Duchy of Modena, the Paris Institution, and that of Groningen show respectively 25, 28, and 31 per cent., while Tuscany and Copenhagen each present 39 per cent. of acquired deafness.

These results suggest several questions for further inquiry; they cannot be accidental; variations so great must have adequate causes. If geographical position could have any influence, it might be adduced that the United States and Germany are both continental, while Ireland, with results so opposite, is insular; but Great Britain is also insular, and presents the medium ratio between the two. The Anglo-Americans, the Germans, the Britons are all of the same mixed Teutonic race; the Irish have in them the Celtic element; the isothermals which pass through the United States also enclose Germany, the south of Ireland, and the south of England. The populations are subject to similar diseases, and have equal advantages of medical aid in cases of illness—yet deafness supervenes upon one or other disease twice in Germany for once in Yorkshire, twice in the United States for once in Glasgow, four times in Connecticut (Hartford) for once in Ireland, and three times in the North of England (Newcastle) for once in Ireland. Brighton, representing the counties of Sussex, Hampshire, and Kent, presents a similar result to Newcastle-on-Tyne. Why there should be two cases of acquired deafness in Tuscany and Belgium for one at St. Petersburg, or why Belgium, itself below the average, should have two for one in Ireland, is a curious matter for future research.

The deaf and dumb are found chiefly among the poor in England, and it is probable that deafness will diminish from the great attention now given to this class, whether within or out of unions; in this respect the very poor are better cared for than those just above them, who never seek parochial aid; probably better, in the matter of medical attendance, than the well-to-do scattered rural population, and this circumstance alone will tend to prevent the supervention of deafness from suppressed eruptions in various diseases. The attention of the physician is not only directed to the cure of the present disease for which he is immediately consulted, but also to the prevention of any evil consequences which might follow such disease. Can it be possible that in the wilder districts of Germany, and in the newly settled counties of the United States—from the difficulty of procuring prompt attention, or the distance of a medical practitioner, disease is often suffered to have its way, and is then followed by consequences which the exercise of timely skill might have averted! This cause has doubtless operated, and may still operate among the rural populations of England. Why does it not produce a larger proportion of acquired deafness in Ireland?

It is observed by Mr. Buxton, the head-master of the Liverpool Institution for the Deaf and Dumb, in a paper published in the Liverpool 'Medico-Chirurgical Journal,' January, 1859: "It is certainly remarkable, that while, according to the ascertained facts, not half so many children are born deaf in any given population in the United States as in Europe, still the excessive prevalence of deafness from disease or accident, brings up the proportion of deaf-mutes to the whole population to very nearly the same ratio which is found among ourselves. In this county of Lancaster it is 1 in 2045, and for the whole white population of the United States it is 1 in 2152." The thirty-fifth Annual Report of the New York Institution compares the United States in this respect with Europe: "In Europe generally, the chances of the birth of a deaf-mute child are more than twice as great as in the United States, or 615 in a million against 278 in a million; but the chances of the loss of hearing after birth, are in Europe generally much less than in the United States, namely, 154 in a million there, and 222 in a million here; while in Ireland this proportion is only 80 in a million."

The Commissioners' Report on the status of disease in Ireland, supplies a hint respecting acquired deafness which ought to be regarded with special attention: "Comparing the congenital with the acquired cases, we find some remarkable differences, caused by localities. In the former class, the proportions are 1 in 1872 in the civic, and 1 in every 1517 in the rural; whereas in the latter the reverse obtains, that class being in the proportion of 1 in 9519 in the civic, and 1 in 11,749 in the rural—the congenital form of disease existing most amongst the rural population; and that acquired after birth prevailing most in crowded cities and towns, where children and young persons are particularly exposed to accidents, scrofulous affections and deleterious influences arising from density of population, unwholesome food, impure air, and insufficient sewerage. Moreover, the populations of cities and towns being in great part recruited by immigration from the rural districts, the deaf and dumb are more likely to remain with their friends in their native homes than those possessing speech and hearing."

Respecting the diseases on which deafness followed, we have the following information from various institutions; the heads adopted by Mr. Toynbee, though too few, have been adhered to in Tables V. and VI., among other reasons from the immense variety of causes assigned for the malady in other tables, but in Table VII. the heads of the Census Commissioners for Ireland are followed:—

It is impossible to say from any existing data, whether boys or girls are more liable to the infirmity of deafness arising from other diseases. The Irish Report gives 419 cases of acquired deafness, in which the sex is distinguished; of these, 216 are males, and 203 females. It is, however, remarked, "that according to the present census there is rather an undue proportion of males over females in Ireland." Parents and nurses have the popular opinion that it is more difficult to rear boys than girls—that a girl will battle through a severe illness, where a boy would fail to do so—that a boy would be left with disease upon him, when a girl would be free from any secondary complaint; there are doubtless cases, where life is saved at the expense of one or other of the organs; but which sex most readily yields to the lesser deprivation to prevent the greater, must at present remain uncertain. The Yorkshire Institution has had under instruction 300 boys and 234 girls, among them were 141 cases of acquired deafness; 84 of these cases were boys, and 57 were girls—a fair relative proportion of either sex, namely, 60 per cent. of boys, and 40 per cent. of girls.

Efforts can only be made to prevent a recurring calamity, when its extent and the external circumstances tending to produce it are known; the various diseases favourable to the supervention of deafness have been named, and the next circumstance which claims notice is the age at which experience has shown the greatest liability to the influence of disease arises. It might be wished that all institutions supported by the state or by public benevolence were required to record such facts, as far as possible, for the general welfare, then would our information afford more conclusive results—

Provided the due proportion of the 120 under the age of 3 years, for Ireland, were distributed under 1 and 2 years, it would be at once manifest that the most fatal time of a child's life for the acquisition of deafness is that between 1 and 2 years of age, and that the next most dangerous period is between 2 and 3; after 5, the liabilities decrease materially. It will be evident then, that great care should be exercised by parents during the continuance and development of all diseases to which children are subject during the first quinquenial period of their life, and more especially with reference to those diseases which are shown in the previous tables to be favourable to the supervention of deafness.

The tendency of deafness to run in families is well known. The Report of the Belfast Institution for 1854 shows, on a list of 68 pupils, *one* instance of 5 (all) in a family deaf and dumb, *four* cases of 3 in a family, and *ten* cases of 2 in the same family. The 534 pupils who have been received into the Yorkshire Institution have arisen out of 416 families; of this number, 342 had only a single case of deafness among their children, the other cases arose out of 74 families—45 of which had *two* each (90), 18 had *three* each (54), 7 had *four* each (28), and 4 had *five* each (20), making 192 cases. Of the Birmingham pupils, 412 were received out of 369 families; of these, 305 had each *one* deaf and dumb, 43 families had *two* each (86), 15 had *three* each (45), 4 had *four* each (16), one had *five* (5), and one had *seven* (7). The 239 pupils of the Exeter Institution have been received out of 164 families, 149 were single instances in the family, 20 families had each *two* (40), 12 had each *three* (36), and 4 had each *four* (16). The thirty-fourth Report of the Glasgow Institution shows that in 298 families there was *one* case in each, in 36 families, *two* in each (72), in 20 families, *three* in each (60), in 3 families, *four* in each (12), in one family *five* (5), and in one *seven* (7), making 454 cases of deaf and dumb in 369 families. The Report of the London Asylum for 1859 shows a selected list of 23 families, containing 160 children, of whom 105 are deaf and dumb.

The thirty-fifth Report of the New York Institution contains much interesting information of the tendency of deafness to run in families, with especial reference to the pupils of that and other institutions in the United States, but space forbids our extracting any portion; enough has been shown above to illustrate this part of the subject, except that it seems desirable to insert the following table (in col. 411) from the census of Ireland, which is introduced in the Report by these observations: "In 3415 instances of deaf-mutes, concerning whom the particulars were available, we have acquired the information shown in the annexed table, with respect to the numbers of which the families consisted in which one or more mutes were born in each. From it we perceive that families consisting of five, six, seven, and eight, presented the greatest number of mutes. The family position of the deaf and dumb is also shown in it, as well as in the foregoing Table. In one instance, two mute children, one the tenth and the other the last, occurred in a family of twenty-nine, all born of the same parents; the twenty-ninth child, now aged fifty-five, is still living in the county of Cork."

We have now to consider some of the causes which are productive of deafness. The laws which influence the physical condition of mankind are becoming better known than they were formerly, and all new discoveries which tend to the amelioration of "the ills which flesh is heir to," are appreciated and applied as opportunities arise. Some of these evils are transitory, and yield to the efforts made for their relief; others, though permanent, may in many instances be divested of their worst character; some are to a large extent preventible, and among this class deafness, both in its congenital and acquired forms, may be placed. The condition of things necessary to bring about such a result may be aided and encouraged by wise legislative enactments, by increased knowledge, and a willingness to observe the laws which govern and regulate life and health. When it is generally admitted that obedience to these laws is favourable to soundness of body and mind, and that a disregard of them brings its own punishment in the form of disease, and early death, we may hope that many of the afflictions under which mankind labour will pass away or suffer diminution.

The principal ascertained causes of congenital deafness are hereditary transmission, consanguine marriages, feebleness of constitution in the parents, scrofula, the influence of locality, and the ill-health of or accident to the mother during pregnancy. The experience of our institutions at home and abroad, and the researches and opinions of scientific men have accumulated evidence on all these causes which entitles them to separate consideration. The results of such researches and opinions will be given, but only to such an extent as can be borne out by the confirmatory experience of the writer. Cases similar to those to be adduced are of constant occurrence in all institutions for the deaf and dumb, and might be multiplied to an almost indefinite extent. The physical history of deafness has attracted much attention during recent years, and the surmises of a quarter of a century ago, have now in many instances, become established facts.

Several cases of the transmission of deafness through three generations are known to the writer of this article; evidence of a similar nature from other sources is proof sufficient that one of the main causes of deafness is *Hereditary Transmission*. "It has been clearly ascertained," says Mr. Harvey, 'On the Ear,' "that the most common cause is a strumous and delicate habit of the body, generally hereditary." An important table is given in the census returns for Ireland, "showing the result of hereditary predisposition, or family peculiarity in the production of congenital muteism. From its arrangement we learn that in 329 instances, numbering 471 persons born in families some of the previous members or collateral branches of which were mute, 249 persons were born deaf and dumb where the disease appeared to come from the father's side; whereas in the other division, where the affection was transmitted through the female line the number amounted but to 222. Among the examples which are given illustrative of this table we find the following: "In cases of single congenital muteism, where the relatives were also deaf and dumb, there were by the father's side—in two instances an uncle and an aunt, in one case two grandaunts, in one instance two aunts, in one case an aunt and a cousin, in another case two nieces and a cousin, in another instance six cousins; in three cases there were four cousins; in eleven instances, three cousins; and in nine cases two cousins, all deaf-mutes. Where two of the family were affected with congenital deaf-dumbness, in two instances four cousins were in a similar condition, in two cases three cousins were deaf and dumb, and in four instances two cousins were thus afflicted. Where three cases of congenital deaf-dumbness occurred in the same family, in one case the great-grandfather had been deaf and dumb, in two instances two grand-uncles had likewise been deaf-mutes, and in five cases two cousins were in a similar condition.

Where the relationship came by the mother's side, there were in cases of single congenital muteism, one instance of a niece and one cousin; eight cases where three cousins were deaf and dumb; and fourteen instances where two cousins were thus affected. In cases of two mutes in the same family, we find that in one case two aunts were also deaf and dumb, in one case three cousins, and in four cases two cousins laboured under the like defect. Where three mutes occurred in the same family, in one instance an uncle and an aunt, and in another a half-uncle and an aunt, were deaf and dumb; and two cases presented two cousins also deaf and dumb." The thirty-fourth Report of the Glasgow Institution (1855) gives cases similar in character to the above, from the records of that institution, and every school of the kind could supply facts bearing on the hereditary transmission of deaf-dumbness.

Consanguine Marriages are, next to hereditary transmission, perhaps the most fertile source of deafness. Every institution in the kingdom bears witness to this fact in the numerous cases of pupils who are the offspring of first cousins. And deafness is not the only evil result; idiotcy, blindness, feebleness of frame, insanity, the death of children in early life, and various physical imperfections, such as club-foot, hare-lip, and spinal deformities are too often the result of such marriages. Mr. Buxton says, "In an inquiry which I made sometime ago, from a large number of persons, I found that about every tenth case of deafness resulted from the marriage of cousins;" and Dr. Peet, of the New York Institution, confirms this ratio; the writer's experience is very similar, and has extended to other mental and physical defects, as well as to deafness, as a common result of such marriages. The Irish Commissioners report on this branch of their inquiry as follows: "Among the predisposing causes of hereditary disease, the too close consanguinity of parents has long been looked upon as paramount, and consequently, an inquiry was made as to its probable effect in producing deaf-dumbness. Returns of this nature must be expected to be deficient; still, 170 instances were recorded, in which the parents were related in the degrees of first, second, or third cousins. The result of these intermarriages was 109 cases of *one* in a family deaf and dumb, of which ninety-four were congenital and five acquired; three were dumb only, and seven dumb and idiotic. Thirty-seven cases of congenital and one of acquired deaf-dumbness occurred, where *two* of the family were affected, including four out of the fifteen cases of twins already specified. Of the remainder, seventeen instances occurred in which *three* of the same family; and three where *four* in the one family were deaf and dumb. In one of the instances where *six* in the family were deaf and dumb, and in the cases of both seven and eight deaf and dumb in families, the parents were also nearly connected. These numbers include, not merely the living upon the night of the 30th of March (when the census was taken), but all the children living or dead, born deaf and dumb of the same parents."

A writer in the 'British Quarterly Review' (No. LVII.) has taken up this subject in its many bearings, and as our own experience confirms his statements, we do not hesitate to quote them: "Popular opinion and scientific induction equally lead to the impression, that although one marriage between near relatives may be unattended by evil consequences immediately perceptible, yet it is very rare that the second or third is so innocent. There usually arises amongst the children resulting from such unions a tendency to disorders, functional or organic, of the nervous system, or of the nutritive organs, tending in the former case to unsoundness of mind, and in the latter to conditions bordering on scrofula, or an allied affection. M. Devay found in the children proceeding from 121 consanguine marriages, twenty-two cases of sterility (actual and virtual), twenty-seven cases of various deformities, and two deaf-mutes. Dr. Boinet knew five idiots in five different families sprung from this sort of marriage. A celebrated lawyer, married to a cousin, lost three children from hydrocephalus. A manufacturer at Lyon, similarly married, had fourteen children; eight died of convulsions at an early age; only one survived; the remainder died of scrofulous affections. In our own circle of acquaintance we know several families where there is an idiot child, or where several of the children have the most strongly-marked nervous peculiarities, to which the parents and the ancestry were strangers, and for which there seemed to be no plausible reason, except that their parents were cousins, and that the families had been in the habit of intermarrying." The writer of this article has, for several reasons, preferred giving the above extracts to detailing similar cases which have come within his own observation, but he is acquainted with more than fifty instances in which cousins have intermarried, and whose children have been visited with one or more of the evils above alluded to; he, therefore, regards such marriages as the transgression of a natural law, which is followed by its own punishment.

The records of every institution for the deaf and dumb, and the observations of individuals who have applied themselves to this inquiry, show that constitutional feebleness in one or both parents is a cause of deaf-muteism. In every institution there is a larger proportion of orphans and half-orphans than would be found among the children in an ordinary school, and also a larger proportion of parents labouring under some physical infirmity. On one of these points, the New York Report, to which we have before referred says, "We have noticed that a large proportion of our pupils, perhaps one-fifth, had lost one or both parents before they came to school; but we have no data to show that this is a larger proportion of orphans and half-orphans than would be found on an average in a promiscuous collection of children who were not deaf." To this testimony it may be added, that one-fourth of the children in the Yorkshire Institution (1858–9) had lost one or both parents in early life, a sure indication of feebleness of constitution, and that a certain number of those living were of delicate frame.

Scrofula in parents, transmitted to the offspring, is generally admitted to be a cause of deafness; it is well known to the medical attendants of all institutions for the deaf and dumb, that strumous affections are common among the pupils, and that they are by no means confined to the congenitally deaf; in some of the cases of children born deaf, unhealthy parents have doubtless originated the disease, independent of any hereditary deafness. Scrofula and consumption, and scrofula changing into one of the protean forms of consumption, or exhibiting itself in glandular swellings, can scarcely fail to be transmitted from parent to child. At the same time there are many apparently healthy parents, and also parents known to be free from any disease, whose children are unhealthy, which can only be accounted for on those obscure physiological conditions which constitute what is called by breeders of animals, a bad cross.

The influence of *locality* has often been assigned as one of the predisposing causes of deafness. A spontaneous disease seems to arise in such cases which may become hereditary, and an accidental circumstance of this nature may favour an acquired peculiarity which may be transmitted to generations. Several cases are on record of the successive inhabitants of damp houses having deaf and dumb children, who were previously free from any predisposition to deafness. Our own experience has shown that a large number of the children of the Yorkshire Institution were born on the eastern side of the mountainous district, extending from Derbyshire, through Yorkshire, into Cumberland; the institutions of Birmingham, Manchester, and London, have received pupils from the other side of this chain of hills; and thus to a certain extent the theory of the Abbé Daras, and the correctness of the observations in the Irish census alluded to in the preceding article, are confirmed. The goitrous neck in Derbyshire, in the Swiss Alps, and in certain parts of Hindustan, is attributed to local influence, and the offspring of parents thus afflicted are subject to those hard tumours about the neck, ears, and chin, while many of them are deaf and dumb.

The *ill-health of, or accident to the mother during pregnancy*, is often mentioned as one of the causes of deafness in the offspring. Mr. Buxton, the principal of the Liverpool school for the deaf and dumb, mentions some of these cases, which we give in nearly his own words. "The Irish Census Returns record 127 instances in which the deafness of the child was ascribed to fright, experienced by the mother before its birth; but though subsequent inquiry was made into a sufficient number of these cases, in order to obtain some trustworthy information as to the causes of fright, no result was arrived at which was worthy of detailed publication. . . . At Leipsic, in three cases of congenital deafness, the misfortune was ascribed to the fright of the mother, and in three others to mechanical violence—one before birth, and two from difficult delivery. At Groningen, the mothers of sixteen affirmed that they had been frightened during pregnancy by the hoarse cries of a deaf-mute, or pretended deaf-mute. Two women of distinguished families, and of delicate constitution (!), ascribed the misfortune of their children to the impression received by witnessing the performance of the drama—the 'Abbé de l'Epée.' Another French lady of rank, assigned the deafness of her child to the lively emotion (!) which she experienced from the circumstance of king Louis Philippe having considerately offered her a chair, upon some public occasion, when she was evidently unfit to bear the fatigue of standing. M. Herbert Valleroux, in his work on Deaf-Dumbness, mentions that several examples of the effect of mental impression are known to him, one instance being that of two children, whose mother ascribed their privation to a paroxysm of anger, experienced during her pregnancy. In America, instances are known in which a mother supposed the deafness of her offspring to be owing to such causes as the following: stopping the ears that she might not hear the screams of an elder child undergoing a surgical operation, or the cries of a dying child; frights received from deaf-mutes or from persons pretending to be such; the sympathy or shock excited by seeing deaf-mute children for the first time; and the fear when one child has become deaf by disease or accident, that the next comer might be *born* so. The latter reason has been frequently assigned as one of the causes for the existence of more than one deaf child in the same family; as if excessive anxiety and fear begot the very evil it dreaded, and thus 'ran to meet what it would most avoid.' A woman living in one of the eastern counties, who had three children born deaf, stated that before the birth of each, she had been alarmed by a deaf and dumb beggar. After the birth of the third, she never saw the man again, and all the children she had afterwards possessed their hearing perfectly. Another woman who had three or four deaf children out of six, stated that before the birth of the first she was summoned to the help of a neighbour who had been seized with a fit, which rendered her speechless, and shortly proved fatal. The sight so affected the expectant mother, as to deprive her of speech for several hours; her eldest child, who was subsequently born, proved deaf and dumb, as were also her third and fifth; the sixth died before the fact could be ascertained; the second and fourth heard perfectly." Some of the above cases are cited in the Report of the New York Institution, where it is very properly remarked, that "it may allay the anxieties of mothers on this subject to learn, that whether we call such cases of deafness *effects* or mere *coincidences*, they are comparatively infrequent, amounting at the most to one case in twenty."

The only other branch of inquiry coming within the scope and space assigned to this article, is that of the *marriage* and *intermarriage* of the deaf and dumb. How truly does the experience of all our institutions prove the correctness of the observation in the Census Report for Ireland—"the defect is seldom transmitted direct from deaf and dumb parents to children." How few of the pupils in our schools are the offspring of deaf and dumb parents; there are exceptions, but these only prove the position. The Principal of the Hartford Asylum (Connecticut) says—"In only a few instances have we known it transmitted from parents to their children." The Principal of the New York Institution says—"We can show that it is much the most common for the children of deaf-mute parents to possess the faculties of which their parents were deprived." Among the 534 pupils of the Yorkshire Institution there have only been two cases in which one of the parents was deaf and dumb, and two instances in which both parents laboured under this infirmity; in one of the former class there were three of the children deaf and dumb, in one of the latter all the offspring, four in number, are deaf and dumb.

Thirty-four of the former pupils of the Yorkshire Institution are known to have entered into the marriage state; there are probably many others; of this number twenty-four have married deaf and dumb partners, one of these instances is that just recorded of all the offspring being deaf and dumb, but no others are known; the other ten are married to hearing and speaking persons, and we have heard of no case of a child among them labouring under the defect of the deaf and dumb parents. Most of the parents are still young, and they may yet have children inheriting the parental defect.

We conclude then that there are no sufficient reasons why the deaf and dumb should not marry, unless we lived under laws which were designed to exterminate deafness, or to prevent every possible mode of its transmission. Discretion must guide mankind, understanding must keep them in this point as in many other social and physical relations with which laws cannot interfere. We have seen that deaf and dumb offspring are neither the inevitable nor the ordinary result of marriages in which one of the parties is deaf and dumb, but in the case of intermarriage the liability is greatly increased and strengthened. The physical weakness which produced the deafness under which the parents labour has nothing to overcome it, as in the case of only one of the parents being deaf and dumb; and if either the husband or the wife is a member of a family which contains other deaf-mutes in its direct or collateral branches, the probability of deaf and dumb children being produced is thereby greatly augmented. The cases of transmission for two or three generations, known to the writer of this article, are all of this class—all among families which have the peculiar hereditary predisposition to this defect. It is well known, and daily observed, even by non-professional observers, that forms of the body, features, deformities, and physical habits are transmitted from parent to child; that intellectual characteristics are frequently transmitted, that moral qualities and tendencies to vice are inherited from parents, and re-appear in their sons and daughters.

Twenty-five years ago there were few statistical documents to assist us in our inquiries as to the physical condition of the deaf and dumb. Since that time most of the institutions in the kingdom have collected data, and some of them have published the results of their researches. The article written for the 'Penny Cyclopædia,' in 1837, suggested a series of heads as a foundation for such investigations. We are thankful to acknowledge how thoroughly the subject has been taken up in the New York Institution, and the aid we have derived from its thirty-fifth report, so frequently referred to. Mr. Buxton, of the Liverpool Institution, has been a successful labourer in a similar direction; and the reports of the Belfast, Glasgow, and Exeter Institutions have also supplied valuable matter, of which we have availed ourselves in the course of this article.

DEAF AND DUMB, EDUCATION OF THE. Before the practicability of instructing the deaf and dumb was admitted, it was generally supposed that instruction by means of the conventional signs and sounds denominated language was limited to those who could hear. The idea never entered the mind of man, or if it did it was as instantly rejected, that the deaf-mute was not, on account of his deafness, bereft of his reasoning faculties, nor excluded from the means of connecting thought with symbols. It was not till the 16th century that the possibility of carrying forward the process of education in the absence of all hearing, received any serious consideration. Even at the present day there are many persons who are at a loss to conceive not only how abstract notions, but even how the names of palpable objects are made known to the deaf, and at a still greater loss to imagine how they can be brought to use language to express their ideas. Having themselves obtained knowledge through the ear, having been accustomed to impart their thoughts by oral communications, they seem to forget that the mind has intelligence in all the senses connecting it with the external world, and conveying knowledge to those higher faculties which compare, discriminate, and judge. In an intelligent though uneducated deaf person, an observer would find these processes going forward, though confined indeed to a very limited sphere, owing to the poverty of his knowledge, but still knowledge, deduced from observation, limited also by the want of a conventional mode of expressing it. The existence of the reasoning power being thus evident, the means to cultivate it would be the next object for philosophic investigation. That Aristotle had never made these observations and investigations is evident, or he would not have come to that absolute conclusion which excludes the deaf from all participation in knowledge. Among other people of ancient times these unfortunate beings were the objects of a species of proscription, being supposed to labour under the curse of heaven. Previous to the time of Justinian the Roman laws maintain an absolute silence upon the deaf and dumb. They speak frequently of deaf persons, not being dumb; and also of dumb persons not being deaf; but never of those labouring under both these deprivations. The Code (lib. vi. tit. xxii. l. 10) mentions the deaf and dumb in a manner express and special. Five classes of persons labouring under one or both of these deprivations are established. Those who from their birth were deaf and dumb were legally incapable of making a will, or of manumitting a slave, and laboured under other civil disabilities.

The reader will find in the work of C. Guyot, of Groningen, which is a dissertation written in Latin on the legislation relative to the deaf and dumb down to 1824, all that relates to this part of the subject, with a list of authors. Saint Augustine, in the fourth century, declares that the deaf and dumb are shut out from obtaining religious knowledge, remarking "that deafness from birth makes faith impossible, since he who is born deaf can neither hear the word nor learn to read it;" and many respectable ecclesiastics in the time of the Abbé de l'Epée openly condemned his undertaking. The benevolent abbé also informs us that parents considered it a discredit to have deaf and dumb children, and they believed that they fulfilled every claim such offspring could have on them by merely supplying their animal wants, concealing them from the eyes of the world within the walls of a cloister, or in some other obscure abode. He also asserts that in some uncivilised countries the deaf and dumb were in *his* time regarded as monsters, and were put to death as soon as their calamity was ascertained. So that we find naturalists, legislators, divines, philosophers, and even parents, agreeing in the impracticability of conveying knowledge otherwise than by speech, and thereby excluding the deaf and dumb from all means of intellectual improvement.

From the advantages which instruction has afforded to a certain proportion of the deaf and dumb for more than half a century, a tolerably correct estimate may be formed of their capabilities for improvement. The deaf-mute living in society, but without instruction, must be regarded as one of the most solitary and melancholy of beings. He is shut out from all but the most imperfect intercourse with his species; and the very intellect by the possession of which he is raised above the lower creation serves only to heighten his calamity, and to render the sense of his deprivation more acute. His perceptions of external objects are indeed accurate but superficial, and confined to a very small sphere. Of the various arts by which the necessaries and conveniences of civilised life are produced, he can have no knowledge beyond that which is included in the range of his own vision. Animal desires he feels, and he is led by the conventional usages of society to the performance of moral duties and the avoidance of open and flagrant crime. Thus he becomes experienced, as other human beings are, in what is right or wrong. He sees that virtuous actions have a certain amount of reward, in the opinions of good men; for he learns to discriminate between those whose actions are proper and those who do wrong; and again, he sees that in many cases vice meets with disapprobation and punishment among mankind. How this kind of experience shall affect his own conduct must depend not only on the circumstances in which he is placed, as to example and the moral influence of those with whom he has to associate, but also on his own natural tendencies.

The performance of moral duties implies the exercise of intellectual faculties; and from his birth the deaf-mute makes use of his reasoning powers. He is subject to changes of purpose, to changes of feeling, to the passions, the pleasures, and the infirmities common to his species; he is sensible of kindness, and he gives proofs of affection. That such is the state of the deaf and dumb when uneducated might be proved by the observations of their parents, friends, and instructors, in hundreds of instances. That such must necessarily be the case, supposing them not to be idiots, it would be easy to show. We affirm, in contradiction to those who contend that deaf-mutes are naturally more debased than other men in intellect and in morals, that there is not an individual deaf-mute now under instruction—improving, and thereby evincing rational faculties—who, previous to instruction, however disadvantageous the circumstances which attended his earlier years, did not evince moral sentiments and intellectual operations. We have traced the history of many of this class in different ranks of society, from the period when the deprivation under which they have laboured was first ascertained to the time when their direct education has commenced; and we have found invariably that mixture of good and evil in their actions and tendencies which is seen amongst other children. We have also had sufficient proofs of the exercise of intellect even while they were in a state of childhood.

At the same time, it must be acknowledged that the deaf and dumb are generally inferior in their moral and intellectual powers to those who do not labour under the same defect. But this inferiority is only one of degree, and may be satisfactorily accounted for, in accordance with the opinions above expressed. Andral has described the state of an uneducated deaf and dumb person, and to a certain extent we can adopt his sentiments. Experience and observation among this class of persons would have induced this accomplished pathologist to have bestowed on them even a more liberal endowment. "The deaf-mute exhibits in his intellect, in his character, and in the development of his passions, certain modifications which depend on his state of isolation in the midst of society. We find him remain habitually in a sort of half-childishness, and he has great credulity; to balance this he is like the savage, exempt from many of the prejudices which we owe to our social education. In him the tender sentiments are not very deep; he appears not to be susceptible either of lasting attachments or of lively gratitude; pity touches him but feebly; he is an entire stranger to emulation; he has few enjoyments and few desires; and the impressions of sadness but slightly affect him. This is what is most commonly observed in deaf mutes; but this picture is not universally applicable. Some, more happily endowed, are remarkable for the great development of their intellectual and moral nature; there are others, on the contrary, who continue in a state of complete idiocy." ('Dictionnaire de Médecine,' article 'Surdi-Mutité.') This last remark of Andral's requires some qualification. Deaf and dumb persons who possess intellectual faculties are no more liable to become idiots than others whose organs perform their appointed functions. Their powers may remain undeveloped; they may be ignorant of everything which depends on intercourse with mankind; their reasoning may be inconclusive, and their inferences erroneous from their confined observations; but still their mental powers will be called into action, and they will be, to a great extent, under the control of their reasoning faculties. This is not the case with idiots: in them there is a deficiency, more or less, of self-government, and of intellectual control. There are, at the same time, numerous cases of idiots who are *dumb;* not, however, in consequence of deafness, but from their incapacity to understand the meaning of language, to imitate it, and to apply it. These persons cannot be classed with *the deaf and dumb.* It may be this class to which Andral particularly alludes in the latter part of our quotation; for he qualifies his remark in some measure by adding, "The difference in the intellectual and moral nature of man is often primitive, and independent of all external influences." Of the same opinion with ourselves we find Degérando, Bébian (the successor of Sicard), Piroux of Nancy, and all the more successful teachers of the deaf and dumb of the present day, in this country and throughout Europe and America.

Passing over the miracles of our Saviour—when the deaf were made to hear and the dumb to speak, by immediate inspiration—we learn from the Venerable Bede's 'Ecclesiastical History,' quoted by the Abbé Carton in his 'Annual of the Deaf and Dumb and Blind,' published at Bruges in 1840, that a deaf man was taught to pronounce words and sentences by John, Bishop of Hagulstad (Hexham), afterwards known as John of Beverley (BIOG. DIV.), in the year 685. This, and other works of healing, were attributed by the simple-minded Anglo-Saxons to some miraculous power conferred upon the good and sensible bishop for his holy life; but enough is recorded to show that the process was the gradual one afterwards pursued by most of the early professors of the art of teaching speech to the deaf and dumb, and even now followed in some of our institutions. The bishop made the sign of the cross on the mute's tongue, which ceremony is now dispensed with, and then pronounced the Anglo-Saxon word ȝea, yea, upon which his tongue was loosed, and he uttered the sound, or a sufficient approach to it to induce the clever bishop to pronounce letters, syllables, words, and afterwards sentences, which the deaf man imitated, a slow but certain process towards success.

The next mention we meet with of the capacity of those born deaf to receive instruction, is in the writings of Rodolphus Agricola (born in 1442) of Groningen. He does not inform us who was the parent of the art; but he mentions in his posthumous work, 'De Inventione Dialecticæ,' that he had himself witnessed a person deaf from infancy, and consequently dumb, who had learned to understand writing, and, as if possessed of speech, was able to note down his whole thoughts. The truth of this relation was doubted by Louis Vives, of Valentia, who wrote in the beginning of the 16th century; but there is as good reason to put trust in Agricola's account as to join in Vives's disbelief. (See the treatise, 'De Anima,' of Vives, L. ii. c. 'De Discendi Ratione.') Not long after the death of Agricola, and during the life of Vives, the theoretical principles on which the art rests were discovered and promulgated by the learned Jerome Cardan, of the University of Pavia, his native place. He was born in 1501, and died in 1576. Cardan thus expresses himself: "Writing is associated with speech, and speech with thought; but written characters and ideas may be connected together without the intervention of sounds, as in hieroglyphic characters." (See 'Journal of Education,' No. VI. p. 204.) The most noted early practitioner of the art of instructing the deaf was Pedro de Ponce; this fact is authenticated by two of his contemporaries, Franciscus Vallesius and Ambrosius Morales. Ponce was a monk of the order of St. Benedict, at Oña. Morales, in his 'Antiquities of Spain,' thus speaks of Ponce: "He has already instructed two brothers and a sister of the constable, and he is now occupied in instructing the son of the governor of Aragon, deaf and dumb from his birth, as the others were. What is most surprising in his art is, that his pupils speak, write, and reason very well. I have from one of them, Don Pedro de Velasco, brother of the constable, a written paper, in which he tells me that it is Father Ponce to whom he is indebted for his knowledge of speech."

The register of deaths of the monastery of the Benedictines of San Salvador de Oña, informs us of the death of Pedro de Ponce, in August, 1584; it records of him that he "was distinguished by his eminent virtues, and that he obtained a just celebrity throughout the world in instructing deaf-mutes to speak." John Paul Bonet, also a Spaniard, published a work on this subject nearly forty years after the death of Ponce. He had probably heard of the success which had been attained in this infant art; and from tradition he might have gained some glimpses into the methods Ponce had pursued; but it appears that he was unacquainted with those methods in any serviceable form, as he represents himself as the inventor of the modes which he pursued, including mimic signs, writing, dactylology, and the oral alphabet. His work, which was in after-years useful to De l'Epée, is entitled 'Reduccion de las Lettras, y Arte para enseñar á hablar los Mudos.' [Bonet, Biog. Div.] During the time of Bonet, the art was also making some progress in Italy. Several individuals are mentioned in Degérando's work who were more or less engaged upon the subject. Affinate wrote at the commencement of the 17th century on a manner of teaching the deaf to speak; and Fabricius of Acquapendente wrote upon the phenomena of vision, voice, and hearing; and on speech and its instruments. In 1616, Jean Bonifacio published a treatise on the language of action. Pierre de Castro, who was chief physician to the duke of Mantua, instructed the son of Prince Thomas of Savoy, but it is not known on what principles. Pierre de Castro died in 1663. About 1670, Father Lana-Terzi, a Jesuit of Brescia, who is described as "an ardent investigator of nature," employed himself on the subject of giving language to the deaf, and teaching the blind to read and write; his work on natural history, published in 1670, contains some philosophical remarks on the mechanism of speech, so it is concluded he taught on the articulation system.

Many first discoveries were probably made of this art: several of them originated with, or were carried forwards by, philologists, and particularly among the schemers for a universal language. In England, John Bulwer's name must stand prior to that of any other individual as an author on the subject, and his views, as given in 'Philocophus,' are sound and practical. It has often been attempted to place Dr. Wallis at the head of this list of discoverers in England; but Bulwer's 'Philocophus, or the Deafe and Dumbe Man's Friend,' was published in 1648,—several years before Wallis commenced even his treatise on speech, and he did not publish his claims as an instructor of the deaf till 1670. We find on consulting the above-named work of Bulwer's, that chap. xv. contains the relation of Sir Kenelm Digby as to what Bonet had accomplished in Spain; and there is no doubt but Wallis obtained information from the same source, as he was in constant correspondence with Sir K. Digby. [Bulwer, Biog. Div.]

A degree of credit is certainly due to Dr. Wallis for the pains he took to systematise what had been done up to this period, and to bring the philosophy of language to bear upon the art. His two great objects, as stated in a letter to Mr. Boyle, were "to teach a person, who cannot hear, to *pronounce the sound of words*," and to teach him "to *understand a language*, and know the signification of those words, whether spoken or written, whereby he may both express his own sense and understand the thoughts of others." Writing, reading on the lips, and speech, the manual alphabet, logical induction, the natural signs—acquired from the deaf—were the means he made use of. From the accounts which have come to us, he succeeded in his purpose. His pupil, Daniel Whalley, was exhibited before the Royal Society in the year 1662. The priority of his invention was disputed by Dr. William Holder, rector of Bletchington, who asserted that he had, in the first instance, taught Popham, one of Dr. Wallis's pupils, to speak. Holder published his 'Elements of Speech, with an Appendix, concerning Persons Deaf and Dumb,' in 1669, which was some years after Wallis's first writings and practice had been made known.

In the same year in which Wallis published his inventions for the deaf, 1670, George Sibscota issued a little work on the subject, entitled the 'Deaf and Dumb Man's Discourse.' He had learned from the writings of Franciscus Vallesius to what extent Ponce had succeeded. Very little can be gleaned from this work, which consists chiefly of reasoning and theory.

The next author on the subject whose work we shall notice is George Dalgarno. His treatise, though full of the conceits of learning, is essentially practical, and even at the present day it might serve as a guide to an intelligent person who desired to become an instructor of the deaf. The date of this little work is 1680. [Dalgarno, Biog. Div.] Dalgarno announces on the title-page of 'Didascalocophus,' that his treatise is the first (for aught he knows) that has been written on the subject. He commences by showing that a deaf man is as capable of understanding and expressing a language as a blind man, inasmuch as that all information is conveyed to the mind through the bodily organs. He goes too far, however, in attempting to show that the deaf man has even superior advantages in acquiring languages to those of the blind. Dalgarno's alphabet is exhibited in the article Dactylology.

We will now trace the earlier progress of the art in Holland. Peter Montans offered some remarks on the instruction of the deaf so early as 1635. F. M. Van Helmont published in 1667 a small tract entitled 'Alphabetum Naturæ,' in which he shows how the deaf may be made to understand the motions of the organs of speech, much after the manner of others who are taught to read. His book is remarkable for some whimsical opinions on the nature and origin of language; and he mentions instances of the result of his system, too improbable to be received even by the most credulous. In 1690, John Conrad Amman, a Swiss physician, residing at Haarlem, undertook the instruction of a girl, deaf and dumb from birth. He seems not to have been aware how much had been accomplished in this art; his own success was decisive; and while his work was in the press, he became acquainted with the writings of Wallis, and entered into correspondence with him. His essay, entitled 'Surdus Loquens,' the speaking deaf man, was published in Latin. His methods were founded on articulation. Amman requires that his pupil's organs of speech shall be rightly formed; then, he says, "my first care is to make him to sound forth a voice, without which almost all labour is lost; but that one point, whereby deaf persons do discern a voice from a mute breath, is a great mystery of art, and, if I may have leave to say so, it is the hearing of deaf persons, or at least equivalent thereto; viz., that trembling motion and titillation which they perceive in their own throat whilst they, of their own accord, do give forth a voice. That the deaf may know that I open my mouth to emit a voice, not simply to yawn, or to draw forth a mute breath, I put their hand to my throat, that they may be made sensible of that tremulous motion when I utter my voice; then I put the same hand of theirs to their own throat, and command them to imitate me; nor am I discouraged if, at the beginning, their voice is hard and difficult, for in time it becomes more and more polite."

Amman goes on to explain how he communicates the pronunciation of letters singly and combined, in a way sufficiently plain for any intelligent person to follow his plan. He concludes by saying, "If there occurs to anybody anything either too hard or not sufficiently explained, he may expect a more full edition; or else let him repair to the author, who, according to the lights granted to him, will refuse nothing to any man."

At the commencement of the 18th century the art began to attract the notice of the learned of Germany. Very early in the 18th century Kerger commenced the work of instruction at Liegnitz, in Silesia. His sister was associated with him in his labour. He used drawing, pantomime, articulation, and writing; it is uncertain whether he employed dactylology, but he speaks highly of mimic language. Contemporary with Kerger was George Raphel, pastor and superintendent of the church of St. Nicholas at Lüneburg, who had six children, and among them three daughters who were deaf and dumb. Paternal affection made him an instructor of the deaf; he succeeded beyond his hopes, and wrote an account of his proceedings for the benefit of others. His work was published at Lüneburg in 1718. Other teachers in Germany were Otho Benjamin Lasius, the Pastor Arnoldi, and Samuel Heinicke. Lasius confined himself almost solely to the teaching of visible language, as reading and writing, associating the forms of the words with the ideas they were intended to convey. It is said that his pupil made a satisfactory progress, and that at the end of two years she could answer important questions on religious subjects. Arnoldi used the means more commonly employed,—articulation, drawing, dactylology, writing, and natural signs. Heinicke was the instructor at Leipzig of an institution founded by the elector of Saxony in 1772; it was the first established by any civil government. He had announced previously to this time that in the course of six weeks he had taught a deaf and dumb person to answer whatever questions were proposed to him. He used those means which had been employed by previous instructors, and he also placed instruments in the mouths of his pupils to regulate the positions of the vocal organs in emitting sounds. He claimed the honour of invention on many points, and guarded with strict secresy some of his proceedings. He had adopted the philosophic system of Kant, and published some writings relating to it. He is said to have been a man of considerable talent in the instruction of the deaf and dumb, and of an active and indefatigable spirit. In his controversy with the Abbé de l'Epée he certainly gained little credit, either as a teacher of the deaf or as a philosopher. He was the great promoter of the vocal system of teaching the deaf and dumb which is still retained in most of the German schools. Heinicke's grave mistake was, that *articulate words* were the only medium by which *thought* could manifest itself; that the written word is only the representative of articulate sound; that a deaf mute can never become anything more than a writing machine without an acquaintance with spoken language.

France commenced this art later than the other enlightened nations of Europe. Indeed she opposed its progress by those philosophic prejudices which in other countries had been refuted by actual experience. A deaf-mute from birth, named Guibal, had made his will *in writing* so early as 1679, and proofs of his knowledge and intelligence were produced in court, so that it was confirmed. It is unknown who had been his instructor. About the middle of the 17th century several individuals in different parts of France turned their attention to the subject. Those of whom we know most are Father Vanin, a priest of the Christian doctrine; Rodrigue Péreire, a Portuguese; Ernaud, the

Abbé Deschamps, and the Abbé de l'Epée. Father Vanin employed design both for giving information on sensible objects, and also in an allegorical way to illustrate abstract and intellectual ideas. Very crude and erroneous notions must have resulted from a system so imperfect, and so little capable of extensive application. The first person who excited general attention in Paris was Péreire; he obtained the approbation of the Academy of Sciences, to the members of which learned body he exhibited the progress of his pupils. His processes were made a secret even to the members of his family; he however offered to disclose them for a suitable consideration, which was withheld, and the nature of his system is only imperfectly known at the present day. His pupils were highly instructed, more highly perhaps than any of an earlier or a subsequent period. A judgment may be formed of the efficacy of his methods from the report of a committee of the Academy of Sciences, where it is stated that his pupils were able to understand what was said to them, whether by signs or by writing, and that they replied *vivâ voce*, or by writing; they could read and pronounce distinctly all sorts of French expressions; they gave very sensible replies to all questions proposed to them; they understood grammar and its applications; they knew the rules of arithmetic, and performed exercises in geography; and it appeared that M. Péreire had given them, with speech, the faculty of acquiring abstract ideas. The two best known of Péreire's numerous pupils were Saboreux de Fontenai and D'Azy d'Etavigny. The former of these two has written an account of the means pursued by his teacher, for which we must refer to the work of the Baron Degérando before mentioned. It appears that Péreire employed articulation, reading from the lips, the manual alphabet, and a method of syllabic dactylology. By this latter instrument of instruction he was enabled to communicate very rapidly with his pupils, and by the frequent use of words in different combinations a knowledge of their value was imparted to them. Thus the frequent recurrence of words through so rapid a mode of intercourse assimilated the acquisition of language to the ordinary process with hearing and speaking persons. The channel of communication being established, and a copious knowledge of words acquired, the art of the instructor would be little more difficult than that of ordinary education. A few years after Péreire's methods had received the approbation of the Academy of Sciences, Ernaud presented to them a memoir on what he had attempted for the deaf and dumb. The society gave him encouragement, but it appears that the pupil brought under their notice was not far advanced in instruction. Ernaud's attempts were more particularly directed to measures of physical relief; he revived the sense of hearing in some cases where it had been partially lost, and he asserts that he had never met with an instance of total deafness. Articulation was the principal means he employed. In 1779 the Abbé Deschamps published his 'Cours Elémentaire d'Education des Sourds-Muets.' To the education of this class of persons he devoted his life and his fortune. He followed in the track of Amman, giving the preference to articulation and the alphabet upon the lips, over the methodical signs of the Abbé de l'Epée. His establishment was at Orleans, where he received paying pupils, and instructed the indigent gratuitously.

In tracing these early steps in the instruction of the deaf and dumb, we have attended more particularly to the working parts of the different methods by which such instruction was intended to be conveyed. We have passed over the various philosophic theories with which some of these methods are incumbered, because they are either forgotten, or rendered obsolete by recent discovery. Much learning was anciently wasted on subjects in themselves trivial, mysterious, or incomprehensible, yet to such researches we owe much valuable knowledge. It seems that no investigation into the laws of nature, however absurd or unattainable the immediate object of such investigation, is utterly without reward. The alchemists of olden times, though failing to discover the wonderful stone for which they sought, found out new properties, new substances, and new combinations, which cheered their labours and conferred direct benefits on society. So, with many of the writers we have noticed, their speculations, though wild, have not been in vain; the useful parts of their systems have been retained, and are now diffusing good among the class for whom they laboured.

The Abbé de l'Epée was one of the most active and benevolent labourers in this task of humanity. He brought into systematic operation the notions which had previously prevailed on the possibility of conveying intellectual knowledge to deaf-mutes, and added to these stores of experience from the resources of his own highly-gifted and well-disciplined mind. He certainly succeeded to a greater extent than any of his predecessors in enlisting the public feeling in his favour, and in drawing the attention of sovereigns to one of the most unquestionable works of charity and of mercy; yet his name has not been suffered to descend to posterity unstained by obloquy, nor undimmed by malignant censure. It appears that accident first made him acquainted with the deaf and dumb; benevolence led him to the consideration how their wants might be supplied. He remembered that his tutor had once proved to him that there is no more natural connection between metaphysical ideas and the articulated sounds that strike the ear, than between the same ideas and the written characters that strike the eye, and that his tutor drew this conclusion :—that it was as possible to instruct the deaf and dumb by writing, always accompanied by visible signs, as to teach other men by words delivered orally, along with gestures indicative of their signification.

In the early part of De l'Epée's career he met with the work of Bonet before mentioned, and the enlarged treatise by Amman, 'Dissertatio de Loquela.' With these guides, aided by the enthusiasm which formed a part of his character, he pursued his task vigorously and with a certain amount of success; not with the success of some of his forerunners in the art, who had devoted themselves entirely and for years to individual pupils. The abbé had a large number of pupils to whom he devoted his life and patrimony. Every one who has been a teacher knows well the degree of success which he may expect if his whole mind is concentrated upon the improvement of a few individuals, and the difficulties he may anticipate if his attention is divided among a great number of pupils. The abbé appears to have made use of articulation in one part of his career, for he wrote a treatise on the mode of teaching by this auxiliary; this treatise was chiefly derived from the writings of Bonet and Amman. He employed dactylology also in a subordinate degree. Pictures he found an uncertain resource, and only useful in the earlier stages of instruction. Methodical signs, writing, and natural signs, were the means on which he chiefly depended for the conveyance of intellectual knowledge.

In acquiring a second language, those who already possess one have at command a comparative grammar which informs them to a certain extent of the value of words in certain connection with others; but the deaf have no such advantage; their natural and uncultivated language—gesture—is powerless for everything but the expression of their most ordinary wants; they have no separation of their ideas into classes, such as produce the parts of speech in more perfectly formed languages. Adelung mentions the inhabitants of the countries on the Asiatic continent as having " but one sound to signify *joyful, joy, to rejoice;* and that through all persons, moods, and tenses. The mere radical ideas are set down together, the connecting links must be guessed at. They form plurals as children do, either by repetition, as *tree, tree,* or by adding the words *much* or *other*, as *tree much, tree other.*" Mithridates, v. i. p. 18. Thus it is with the naturally deaf, the radical idea is all that their gestural language is capable of expressing until modified by those arbitrary forms of speech which are the accessories of every polished language.

In order to represent the good abbé fairly, we will take two examples of his process of teaching, from the translation of his own work, published in England in 1801. He is about to teach the present tense of the verb *to carry.* " Several deaf and dumb pupils being round a table, I place my new scholar on my right hand. I put the forefinger of my left hand on the word *I*, and explain it by signs in this manner: showing myself with the forefinger of my right, I give two or three gentle taps on my breast. I then lay my left forefinger on the word *carry*, and taking up a large quarto volume, I carry it under my arm, on my shoulder, on my head, and on my back, walking all the while with the mien of a person bearing a load. None of these motions escape observation. I return to the table, and in order to explain the second person," &c. All this is as good as any process employed in the present day, and illustrates the application of *natural* signs. The next example is one in which signs of reduction are employed. M. Linguet had observed that the deaf and dumb were demi-automatons. The abbé addressed him, and a short time after Linguet visited the abbé and his pupils. " I requested him," says the Abbé de l'Epée, " to propose at his fancy, some abstract ideas to be delivered by methodical signs to the deaf and dumb. As, out of compliment, he referred the choice to me, I addressed him to this effect:—'*Intellect, intellectual, intelligent, intelligence, intelligibility, intelligible, unintelligible, intelligibly, unintelligibly, unintelligibility:* here are nine words all generated from "intellect," to be expressed by distinct methodical signs. *Comprehensible, incomprehensible, comprehensibly, incomprehensibly; Conceivable, inconceivable, inconceivably; Idea, imagination, imaginable, unimaginable; Faith, credence, credible, credibly, incredible, incredulous, incredulity:* here, learned sir, is a cluster of abstract ideas, which shall be left to your option.' After some further little contest of politeness, he selected the word *unintelligibility*, doubtless conceiving it of greater difficulty than the rest. It was instantly rendered to the pupil and written down. While he was viewing it with eyes of amazement, I thus resumed, 'Barely to produce the word you specified, learned sir, is a mere nothing. I will now unfold to you the means taken to prompt it by methodical signs; the exposition will not detain you long. Five of these signs were fully sufficient to designate the word; and you saw with what celerity they were given. The *first* signifies " not an external but an internal action;" the *second*, " of reading the mind, that is, exhibiting the disposition of apprehending the things proposed to it;" the *third* announces "the possibility of this disposition," whence arises the appropriate noun-adjective, *intelligible;* which, being a concrete quality, is converted into the abstract by a *fourth* sign, forming *intelligibility;* and a *fifth* sign being added for negation, *unintelligibility* is produced.'" By this and other examples M. Linguet was convinced that his expression was inaccurate and inconsiderate; but we need not follow out the examination which the pupils underwent in his presence. We have quoted this example in order to show the mechanical nature of the signs employed. That these were well qualified for dictation of words was sufficiently proved in the abbé's experience, but the words might be produced by the pupil from the signs of the teacher, without their being understood, just as an ordinary schoolboy, unused to Latin exercises, might, from the dictation of his teacher, produce examples without understanding a single idea which they contained.

In distinguishing gender, the abbé says, "The gender is explained by putting our hand to our hat for the masculine, and to the ear, the part to which a female's head-dress extends, for the feminine." In the English institutions the hand is placed to the beard to denote the masculine, and drawn along the forehead, in allusion to the parting of the hair, for the feminine. The following is the generally received sign for singular and plural: "The elevation of the right thumb designates the singular, the motion of several fingers the plural." The following is also good: "To express doubt, we turn our head to the right, a *yes*, and to the left, a *no*; which of the two will take place we cannot tell; we shall know only by the event." Many similar examples might be adduced: how superior are these to "twirling two fingers round each other while declining, that is, while descending from the first to the sixth," to signify the term *case*; or "the left hand under the right for the noun-substantive," and "the right under the left for the adjective," will be readily perceived.

We do not regard the success of the Abbé de l'Epée as complete, but we are satisfied that he pursued his methods with openness and candour, and with the single desire of promoting the moral and intellectual advancement of the deaf and dumb. Heinicke of Leipzig, and Péreire of Paris, must be regarded as his rivals, but he invited them to a discussion of the merits of the various systems, which they declined. While the good abbé, with that frankness which formed a beautiful feature in his character, solicited the examination and the judgment of the learned upon his methods, his rivals shrouded their proceedings under a veil of mystery. The abbé devoted his life and whole fortune, excepting a bare supply for his own wants, to the service of the class whom he had taken under his protection. Péreire refused to disclose his methods, except for a large recompense; and Heinicke, in addition to receiving payment from the rich, had four hundred crowns annually allowed him by the grand duke of Saxony. Both these persons made the art they professed an interested speculation; the Abbé de l'Epée only tolerated the rich—he was proud of being the instructor of the indigent. His successor, the Abbé Sicard, carried forward the principles of De l'Epée; he instructed his pupils in the elements of composition, a branch of their education comparatively new, and in which Sicard most completely evinced his superiority over his master. Sicard at first conducted a school at Bordeaux; on the death of the Abbé de l'Epée, Sicard was called to fill his place at Paris. The philosophical opinions and penetrating views which Sicard maintained and practised are well developed in his 'Cours d'Instruction d'un Sourd-Muet,' in which is developed the plan on which he conducted the education of his celebrated pupil Massieu. He followed the leading principles of De l'Epée, particularly in employing methodical signs as one of the chief instruments of instruction; he considered well the nature of language, and by his clear and analytical methods of sensible illustration, he contrived to make the leading principles of grammar familiar to his pupils. In the latter years of Sicard's practice he thought more favourably of articulation, as a means of rapid communication between master and pupil, than he had done at the commencement of his career. The Baron Degérando says of his most popular work, "When we read the 'Cours d'Instruction d'un Sourd-Muet,' we almost fancy that we are reading a kind of philosophical romance. It borrows its forms, and creates a similar interest; we find in it something of the romance of the Arabian Theophail ('Le Philosophe Autodidactique'); something which appears borrowed from the pictures of Buffon, the statue of Condillac, and the Emilius of Rousseau; it is a soul which has hitherto slumbered, which awakes; an intelligent life, which begins to develop itself, amid a variety of scenes, to the voice of the instructor; it is a kind of savage, strange to our customs, who is initiated into our ideas, our knowledge, and at the same time into our language. The Abbé Sicard enlarges upon each of these progressive stages, and spreads over them the charm of a drama; he paints with warmth the uncertainties and the joys of the master and the pupil; and he succeeds in thus showing, in an animated picture, definitions and processes which appear the most barren in their nature; he gives a shape to the most abstract notions; it might be said that the Abbé Sicard is the *painter of syntax* and the *poet of grammar*. This work went through several editions, and we need not be surprised at it, for it is not to the deaf and dumb alone that it may be profitable."

Of the 'Theorie des Signes,' a work founded on the principles of the Abbé de l'Epée, we can only give a faint sketch. It is a kind of dictionary, in which the expressions of the face, and the attitudes of the body, for the communication of certain ideas, are described. The arrangement is not the ordinary alphabetical form of a dictionary, but a kind of logical order "more conformable to the nature of things, and the growth and expansion of ideas." The work is divided into twelve classes of things, adopting in each class an alphabetical order corresponding to the French language. These classes are arranged as follows:—

1. Signs of names of the most common objects, and such as come under observation during infantile years; these are the parts of the body, clothing, food, beverages, a town and its parts.
2. Vegetables, comprising forest-trees, shrubs, fruit-trees, culinary vegetables, medicinal herbs, wild plants, &c.
3. Minerals—gold, silver, copper, brass, lead, tin, iron, &c.
4. Of man—ages of man, relationships, school, institution, college, officers, domestics and servants of a house, tradespeople, mechanics, merchants; the liberal arts; titles, dignities in towns, cities, and states, and their functions; terms of war; ecclesiastics, and monastic functionaries.
5. Of God, angels, saints.
6. Of the elements; of fiery, luminous, and watery meteors; the firmament, earth, cardinal points, signs of the zodiac.
7. Parts of the world; names of nations, empires, kingdoms, republics, capitals, principal islands, &c.
8. Numbers, measures, weights, time, money, exchanges, commerce.
9. Organic qualities of man; abstract organic qualities of man; maladies of the body.
10. Qualities of matter; such as strike the senses of man, dimensions, shapes, surfaces, extent, quantity, lines, angles.
11. Physical actions of man, such as are expressed by verbs.
12. Intellectual and moral actions of man, expressed by verbs, nouns, adjectives, and adverbs.

These are the divisions Sicard adopted for his nomenclature, which occupies nearly the whole of the two volumes comprising the work, the latter portion of which is purely grammatical; in it the different parts of speech are considered, not only under a general view, but under certain divisions which indicate their value, and assimilate those which bear a relationship to each other; thus adverbs of *manner*, of *number*, of *place*, of *quantity*, of *quality*, of *interrogation*, of *affirmation* and *negation*, of *time*, of *doubt* and *inquiry*, and of *comparison*, are distinctly and separately treated of. Without questioning whether the classification adopted in the twelve divisions of the 'Theory of Signs' be the best, we may see in such a classification the kind of gradations needful for supplying the deaf with an extensive nomenclature; and though few instructors would make the work a practical one, so far as to adopt the system of methodical signs there developed, yet, as a text-book, it unfolds a plan which any teacher may modify according to his own views. We think the work is less valued than it deserves to be, for as signs will to a certain extent be always in use among the deaf and dumb, especially in those institutions where they are educated, the theory of signs would be found of great use as a work of reference to all teachers. We need not panegyrise the Abbé Sicard; his exertions for the deaf and dumb are well known in this country, which he visited during the political troubles of France in 1815; his merits are acknowledged wherever the education of the deaf is pursued. We have sometimes been surprised that the 'Cours d'Instruction d'un Sourd-Muet' has not been translated into our language. Independent of its novelty and interest as connected with its more immediate design, its gradual unfolding of a great mind involved in moral and intellectual darkness, by a metaphysician of high endowments, presents some interesting psychological facts which would make it serviceable in general education; the illustrations of language and the development of ideas are just such as an accomplished and lively teacher would desire to place before his pupils, to assist in conveying to their minds a just estimation of the value of words, and the knowledge which they serve to impart.

In England, after the time of Bulwer, Wallis, Sibscota, and Dalgarno, the art slumbered for many years. It was revived by Henry Baker, the naturalist and microscopical observer, who taught dumb persons to speak, and of whom it is recorded by Dr. Samuel Johnson, that he once "gave him hopes of seeing his method published;" he however kept the plan he followed secret. Of the extent of his success we know nothing, but it is said that the names of some of the first families in the land are among those of his scholars. [BAKER, HENRY, BIOG. DIV.] About the year 1760, Thomas Braidwood had an academy at Edinburgh, where he taught the dumb to speak, and cured impediments in the speech. He professedly pursued the plan of Dr. Wallis, as developed in the 'Philosophical Transactions.' Articulation was therefore the chief instrument of instruction, and the principal medium of communication between the pupil and teacher. In 1783 Braidwood removed his school to Hackney, where he enjoyed for many years a deserved reputation for his successful application of the discoveries of his predecessors. [BRAIDWOOD, BIOG. DIV.] Under him the late Dr. Watson became acquainted with those principles which he brought to much greater perfection than his predecessor, and developed in his work on the 'Instruction of the Deaf and Dumb,' and which he practised during his long superintendence of the Asylum in Kent Road, London. Indeed Dr. Watson was to Mr. Braidwood what Sicard was to De l'Epée; the disciples in each instance gave solidity and permanence to the systems of their respective masters.

The teachers of the deaf and dumb of the present day are divided, as formerly, into two classes, namely, those who make articulation, and reading on the lips, their main auxiliaries of instruction, but who generally use dactylology and pictures also; and those who depend more upon natural or imitative signs, and who also employ writing, pictures, and dactylology. In only one school in England, that of London, is articulation systematically followed; in all the provincial schools it is discarded as a main instrument of instruction, though in a few it occupies a very subordinate place. In teaching the deaf and dumb, the first object in view is to impart to him the language of his country; the second is, grounded on this—to fill his mind with intellectual, moral, and religious truth. These two objects are generally made to accompany each other; the communication of knowledge in easy language familiarises him with the forms of language, and the exercises themselves are made the vehicle of valuable knowledge. In teaching vocal sounds to the deaf, the eye and the sense of touch are chiefly employed; the letters of the alphabet are classified; the sounds that are labial, dental, lingual, guttural, nasal, and those which are combinations of two or more of these, are taken in such an order that the pupil may discern differences in their similarities, and in some instances the organs of speech are shown, by means of drawings, in the required positions for the emission of certain sounds.

The open mouth, the widening lips, and part of the tongue, may be shown in the pronunciation of *a*, the nearly closed lips, hiding both tongue and teeth in *u*; in *b* the compression of the lips can be accurately shown, and the labial-nasal sound *m*, may be said to be exhibited in the closed lips, and by a line of dots to show the emission of air through the nostrils. It must be clearly understood that such drawings are chiefly useful in showing the positions of the organs.

Accompanying the exercise, the pupil must be made to notice the external organs of speech in his teacher, to feel the vibration with his own hand which sound creates in the trachea, and also to feel those emissions of breath which are caused by the production of certain sounds. He will be made to imitate such utterance; and by the exercise of patience and ingenuity on the part of the teacher, ingenuity chiefly directed to those little arts which refer to the mechanism of speech, and patience that will not be discouraged by repeated failures, the pupil will succeed in imitating what he observes, and in time he will accomplish what is required. In Wilkins's 'Essay towards a Real Character' there is a diagram of the positions of the organs for producing vocal sounds, which may be consulted with advantage, though not in every instance accurate. While a pupil is engaged in acquiring the articulated sounds he may also be employed in writing letters which they indicate, and in learning their shapes by the eye; he may also be initiated in the manual alphabet. In teaching the deaf articulation, the *names* of the letters are not taught, but their *powers;* thus in the sentence, "Fame can charm all;" the vowel *a* has a different sound in each combination, and each sound must be taught and practised separately till it is acquired, and so on with the other vowels; the consonants are classified too, and whether a breathing is required as in f, th, s, sh, p, &c., or a murmuring as in v, th, z, b, d, g, &c., care is taken not to call them by their ordinary alphabetical names. In Edgeworth's 'Practical Education' the consequence of teaching hearing children alphabetic sounds is thus exhibited. A child having learned the alphabet, and having to read the words, *Here is some apple pie*, would, it is fairly enough suggested, pronounce thus: *Acheare ies esoeme apepele pewie.* This is not exaggerated; with hearing children, constant reading corrects the tendency; but numerous instances of this nature must and do occur among the deaf, who in many cases retain the first impressions they receive as to the sounds of letters.

Another primary auxiliary in the education of deaf-mutes is that modification of the language of gesture called natural signs. In this language the deaf and dumb take great pleasure; if unrestrained, it would be their only mode of communication with each other; and they appear to find in its resources all that is necessary to give life and force to their ideas. The quick changes of countenance which they exhibit, the sparkling eyes, the lighted-up features, the sarcasms, the sensibilities thus expressed; the transitions "from grave to gay, from lively to severe," all faithfully portrayed in the ever-varying index of their mind, speak at once in favour of this language as the truest mirror of their thoughts, hopes, wishes, and feelings, and inform us that this language is nature's most perfect, most expressive interpreter. To this rude though powerful mode of intercourse, which all the deaf possess in a higher or lower degree, those who are more intelligent add signs of description, by which they are able to explain facts and circumstances which have been brought under their observation. The teacher takes advantage of this method of communication to add to their stores of knowledge, to enrich and extend the sphere of their thoughts, to give them new food for the mental operations, all of which may be accomplished during the time that words and the language of their country is imparted to them. Thus a conventional language is formed which assists in their intellectual culture, increases their happiness, and shows them in some degree the connection which exists between themselves and the objects by which they are surrounded. In many institutions this use is made of signs: new knowledge is most effectually communicated by their aid. The sixteenth report of the New York Institution for the Deaf and Dumb furnishes an example of which we can avail ourselves to show the great benefit of signs in the business of instruction. The natural signs for the words in which the sense of the sentence is comprised will readily occur to the reader. "Let it be supposed that an instructor should wish to produce the following sentence: 'A horse runs away with a boy, throws him off, and kills him.' It is not at all probable that such a combination of circumstances would occur at the moment, and thus enable him to take his pupils to the window and point them out. He must have recourse, then, to signs. It is immaterial what selection of place and circumstance is made, provided only that the facts to be enunciated are clear and prominent. The scene of the occurrence may be laid in the city. The boy is riding slowly along, staring at the multitude of new objects which meet his view, and wholly forgetful of his horse. Suddenly a military company appears from a cross-street, with drums beating and colours flying. The horse becomes frightened and beyond control: he dashes through the street at a furious rate. The boy clings to the saddle, but is at length thrown with violence on the pavement. The blood is seen spouting from his mouth and nostrils. People gather around and raise him up. They feel his pulse; but it has ceased, and the breath of life is gone: the boy is dead. During this description, the class are looking most intently on the instructor. Every eye is fixed, and every countenance full of expression. He has now obtained everything for which he laboured. Their ideas and notions of the fact are as clear and explicit as his own; and it only remains to express them by written language. To imagine, as some have done, that this process of writing is a *translation* of signs into language, is wholly erroneous. It is no more a translation than the same expression of a speaking child would be, when the casualty should actually occur." To this we will only add, that the rapidity with which such a description is conveyed to the pupils is inconceivably great, and takes very little longer than the communication of the occurrence vocally, in its shortest form. But the disadvantage attending such a mode of intercourse, when a language has to be taught, is not recompensed by its rapidity, as the words and the syntax of spoken languages are not employed in such descriptions; the pupils are consequently left ignorant of the grammatical construction of sentences. It is therefore found necessary to unite natural and descriptive signs with writing or dactylology, in the use of which the idiom of the maternal language is preserved. Most of the English and American institutions employ the signs we have described; this auxiliary is also employed at Paris, at Yverdun, at Vienna, Toulouse, Nancy, Besançon, Bachtelen, Pisa, and at several other institutions. Mimic signs will always possess this advantage to the deaf over every other mode of intercourse, that they present to them a lively picture, in which facts and circumstances can be constantly and instantaneously reproduced; they address themselves immediately to their perceptive powers, and lead them intuitively, and by a direct process, to form just connections and conclusions; while our conventional tongues, whether addressed to them by articulation, by writing, or by dactylology, act upon them by the circuitous paths of association, and the habit which they long follow of converting our language into their own.

One important influence which the mimic language exercises on the intellectual development of the deaf has yet to be noticed. This results from its employment among themselves. Much of the knowledge which the younger pupils of an institution obtain is through this medium. The lessons of the teacher for many months have less influence on the minds of his pupils than the intercourse with their associates. This is a powerful argument for bringing up the deaf and dumb in public rather than in private schools. Independent of the stores of knowledge which an assemblage of deaf-mutes bring from the districts in which they have lived, the fruits of their personal observation and experience, the events that have occurred within the walls of the institution, particularly as they bear upon actual occurrences, are handed down by mimic and descriptive signs from one generation to their successors; and a very valuable and available store of intelligence is thus preserved, which at the same time contributes to the formation of character and familiarises the pupil with the use of this species of language. Respecting *methodical signs*, we need add nothing to what has already been said of the method of the Abbés de l'Epée and Sicard. We think they are not much used at the present time in the education of deaf-mutes.

Writing is employed in all institutions; it is an art which is soon acquired sufficiently well for all school purposes. At first it engages the attention of the pupils, while they endeavour to form on their slates those combinations of letters, the meaning of which has been conveyed to them; and thus it relieves the teacher and employs a new set of faculties in the pupils. This slow but permanent repetition of their lesson assists in fixing the forms, and the matter conveyed by them, in their minds. At a later stage, it exercises similar influences upon them in a higher degree; and it is, besides, the instrument by which they give permanency to their thoughts and observations in those *compositions* which form an important exercise in these seminaries. It is also the medium to which they chiefly have recourse among strangers, and among their friends, if they find their articulation is imperfect, and their signs not well understood.

Dactylology is another auxiliary in almost universal use. For a more particular view of the utility and value of this instrument of instruction we refer to the article DACTYLOLOGY.

Pictures and the art of drawing are valuable helps at the commencement of instruction. A collection of all objects cannot be made, nor can objects be so conveniently referred to as representations of them. Either by reference to pictures or real objects, the first lessons are conveyed to the deaf, and they impart an interest to the exercises which no other means could supply. To those who have not well considered the subject, it is a matter of surprise how much of language can be represented by a graduated series of engravings, or even by the rude sketches which a teacher can draw upon his tablet whenever they are wanted, to elucidate the subject which he is desirous to impress on the minds of his pupils. In the work of Bébian, the successor of Sicard

('Manuel d'Enseignement Pratique des Sourds-Muets'), the pictorial art is employed to exemplify substantives, their gender and number, adjectives, the cardinal numbers, fractional numbers, verbs neuter and active, personal pronouns, prepositions, articles, and degrees of comparison; many other portions of language may be explained by diagrams. Drawing is thus of essential service, and the pupils often have recourse to the advantages it offers for any communications which they think will be better comprehended through its medium than others. This art is therefore encouraged, and in nearly all institutions direct instruction is given to the pupils from an early period of their education.

The auxiliaries we have now indicated are used for the conveyance of all kinds of knowledge; in some branches of study one may have a preference to others, from its being better adapted to their elucidation. Thus geography will always be taught from maps, geology from sections, geometry from diagrams; pictures will be used to describe historical events; and signs will be in requisition for the illustration of the arts and trades of men, as well as for showing the manners and customs of distant nations. Collections of metals, minerals, vegetables, animals, animal substances, vegetable substances, are of the highest value, and furnish direct evidence of properties and changes which cannot be described. It will even be necessary occasionally to call in the assistance of the workshop and its implements, the laboratory and its apparatus, in order to perform experiments, and to exhibit processes before their eyes; and while the excitement prevails, to make use of the opportunity to communicate not only knowledge, but the primary aim of all instructors of the deaf and dumb—*language*. Having the latter, the attractive form in which knowledge is presented will raise in them a desire to possess this also, and the object of the teacher is fully accomplished.

It has been already mentioned that Heinicke was the great promoter in Germany of the system of vocal articulation and reading on the lips still retained in the German schools, and also adhered to in the London asylum, but only exceptionally followed in the other schools of the United Kingdom. In the year 1844, in consequence of some statements put forth by the secretary of the Massachusetts Board of Education, the directors of the New York Institution felt themselves called upon thoroughly to investigate the results of the vocal system pursued in Germany, as compared with the modes of instruction adopted in the New York and other American institutions, which are generally those of the provincial schools of this country. It had been asserted officially, that the institutions for the deaf and dumb in Prussia, Saxony, and Holland were decidedly superior to those of America; that the German instructors possessed the art of teaching their deaf and dumb pupils to speak substantially in all cases as other men speak, and thus restoring them to society. And these assertions were put forth with that apparent novelty which implied that the American teachers of the deaf and dumb were wrapped up in comfortable ignorance of a controversy at all times interesting, but which at the time had been all but unanimously decided in England and America, as well as in most of the other countries where the education of the deaf and dumb had made any progress.

The New York board of directors, therefore, availed themselves of a visit to Germany of the Rev. George E. Day, to set this vexed question at rest. No man could have been better qualified for such a mission. He had been for some years a teacher in the New York Institution, and he was familiar with both the theory and the practice of deaf-mute instruction. He possessed a competent knowledge of the French and German languages; and his object in going into Germany was the prosecution of literary and theological studies. He had also powers of discrimination and philosophical habits, which would render his examination of the subject thorough and his conclusions accurate.

Mr. Day received from Mr. Peet, the principal of the institution, a letter of instructions, in which he was appointed the delegate of the board to the schools for the deaf and dumb in Europe, while his attention was to be specifically directed to those in the German states. He is reminded that the system of instruction adopted in America is that technically known as the French system of De l'Epée and Sicard, as distinguished from that of Heinicke and Braidwood; that its chief characteristic is the employment of an expanded and improved language of gestures as the *principal means*, while the acquisition of written language is the *end* of instruction; that the system of Heinicke is that which differs from it most obviously: and he is directed to state in describing the systems of different institutions, what are the *ends* proposed, the *method* in which the difficulties of language are presented, the *processes* employed, and the *instruments* of communication between teachers and pupils. As to the specific object of his mission, Mr. Day was to ascertain in what schools for the deaf and dumb in Europe articulation was taught, either as a general acquisition or restricted to a class; if taught in a class, whether to those partially deaf, or to those who had learned to speak before losing their hearing; the extent to which pantomime is used in articulating schools; whether lessons given by the teacher who employs gesticulation would be equally intelligible without it, the words being merely read on the lips; if the colloquial intercourse of pupils of articulating schools in their hours of recreation is more frequently carried on by gestures or by the voice and reading on the lips; if the deaf and dumb seem to take pleasure in exercising the faculty of speech; if complete success was attained in all cases in any institution; the proportion of success and of failure, distinguishing such proportion in those who had been deaf from birth; if the articulation of deaf-mutes who had left school some years was easy and agreeable to strangers, or whether they had discontinued the practice of speaking; to what extent reading on the lips is practicable, and the assistance these acquisitions give to pupils in their future studies; the effect of articulation on the health and physical development of deaf and dumb children; and finally, Mr. Day was instructed to inquire in what language articulation and reading on the lips have been found most ready for the deaf and dumb, and in what the most difficult; whether such difficulties arise from the number of silent letters, the various sounds given to the same letter, irregularities of orthography, capriciousness of accent, &c. &c., and how the English language will compare in these respects with the German, French, and other European languages.

The above is a mere skeleton of Mr. Peet's letter. In the condensation which we propose to give of Mr. Day's able and copious report, we must be proportionately brief, confining ourselves almost exclusively to the subject of articulation and reading on the lips.

Mr. Day arrived in England, according to his own statement, at the time of the Midsummer vacation. He visited several of the English schools, but does not mention which of them, and then passed over to Paris, as a centre of information respecting the European schools. We gather from the following passage that he visited the London Asylum: "Even in the London Institution, where articulation is professedly taught, the principal assured me that the object in view is by no means to teach all the scholars to speak, but only to understand by the motion of the lips what is said by others. According to a very intelligent gentleman who had been ten years connected with that institution, not one-fourth can be taught to speak. That such should have been the history of articulation as a branch of instruction in Great Britain, will not appear singular to those to whom the great and peculiar obstacles to be encountered in teaching the pronunciation of our language are familiar."

Instruction in articulation had been recently introduced in the school at Paris to a limited extent,—namely, to those who retained some degree of hearing, who had learned to talk previous to their deafness, or who were otherwise promising candidates. "Of the 115 male pupils, a class of 29 receive instruction in articulation an hour a day. These are divided into two sections, the elder of which have been under instruction not far from a year. The younger division of 15 had so far failed to encourage expectation of their future progress, that the attempt with eight of them was about to be abandoned." Their instructor remarked, that all that could be then said was, that the most promising might be able at least to make themselves understood; that this kind of instruction was peculiarly laborious; that the French as well as the English language, on account of its irregular orthography in respect to pronunciation, interposed great obstacles in the way of success. In a few other schools in France,—those of Bordeaux, Toulouse, and Nancy,—instruction in articulation is given to those who it is supposed can profit from it.

Mr. Day found several German theories of instruction, in all of which prominence was given to articulation as a principal auxiliary. "First is the *Saxon school*, the oldest in Germany, the one whose principles and processes agree most nearly with those of Heinicke. Of this class of instructors, now very small, Mr. Reich, of Leipzig, may be considered as standing at the head. Next in age comes what may be called the *Wurtemburg school*, of which the Rev. Mr. Jager, for many years principal of the Royal Institution at Gmünd, may be regarded as the founder. The teachers, who fully embrace his views, are principally to be found in Southern Germany. Thirdly must be reckoned what may be termed the *New Prussian school*, from the recognised expounder of its principles, Mr. Moritz Hill, the intelligent instructor in the Teachers' Seminary at Weissenfels, in the Prussian province of Saxony. A number of young men embrace his views with ardour, and are carrying them out with zeal.

In respect to the main *object* to be secured by the education of the deaf and dumb, the larger portion of the German instructors perfectly agree. Some, indeed, attach so much importance to the teaching of articulation, as to leave the impression that they recognise no higher aim; but those who take a wider view, regard a preparation for intercourse with society as only a part of the object, and justly remark, with the excellent Mr. Jager, that the main end of the instruction of the deaf and dumb is to prepare them for this world and the next, for life and for death. The *means* are instruction in the ordinary branches taught in the common schools of the country, under such modifications as are considered most suitable for persons in their condition. The *instruments* are, present objects, models, pictures, pantomimic signs, articulation, reading on the lips, and writing. In respect, however, to the relation which these instruments bear to each other, the different teachers widely differ. "Artificial and arbitrary signs, as also the finger-alphabet, the German teachers agree in theory in rejecting, on the double ground that they are not understood among those with whom the deaf-mute is to associate in after-life, and that they hinder the progress of the pupil. There are now only two or three schools in Germany, so far as I know, in which the manual alphabet is at present employed. These justify its use on the ground that words given to the deaf-mute for the first time orally, are not certain to be understood.

and that the manual alphabet is a convenient means of supplying the defect."

In the following descriptions Mr. Hill's course has been generally preferred, as being on the whole as successful as any. In order to be a successful teacher of articulation, according to the German measure of success, it is necessary to have, *first*, well-formed organs of speech, and a correct pronunciation; *secondly*, an accurate knowledge of the vocal organs, and of their positions and motions in the production of different sounds; *thirdly*, skill in making the deaf-mute perceive the different motions of the mouth, and teaching him to imitate them himself; and finally, infinite patience. In order to make the pupil acquainted with the position of the organs necessary for the production of the sounds required, the teacher places his own organs in the necessary position, makes the scholar by sight and feeling notice these positions; encourages him to do the same himself; helps him when he does not succeed; and finally, proceeds from simple to composite sounds; that is, to syllables and words, and from these to sentences. As *apparatus*, a looking glass, in which the pupil may view the position of his own mouth, as compared with that of the teacher, and a paper-folder used to direct the motions of the pupil's tongue, are generally employed. The process of instruction is exceedingly slow, and requires that only one scholar be taught at a time. In Germany, both in the schools for hearing children, and the deaf and dumb, the powers of the letters of the alphabet are taught instead of the name-sounds. For deaf-mutes, indeed, no other course would be practicable.

The best *order* in which to teach the alphabet varies somewhat with different pupils, and hence it is the practice of the best teachers, as early as possible, to try all the sounds of the alphabet, in order both to test the pupil's capacity and ascertain to what points attention must be specially directed. Generally, however, experience has shown the following order to be as successful as any, namely, *h*; *a* (*ah*), *u* (*oo*), *i* (*ee*), *p*, *t*, *k*, or *b*, *d*, *g*; *o*, *e* (*a* in fate); *au* (*ou*), *ai* (*i* in lion); *f*, *s*, *ch* (the last a peculiar sound); *w* (nearly *v*), *f*, *j* (*y*); *ä* (or *æ*); *b*, *d*, *g*, or *p*, *t*, *k*; *sch* (*sh*); *m*, *n*, *ng*; *l*; *r*; *ö*; *ü* (the two last have peculiar sounds). Next follow the consonants placed *after* the vowels, and the forming of significant words, as *af*, *of*, *ruf*, *ohr*, &c. The main object here is rather mechanical readiness in speaking than acquaintance with the meaning of words.

Mr. Day comments on the patience required, the mistakes into which pupils fall from the want of ear to guide them in pitch and intonation, the high sounds amounting to a scream, the low ones little better than a growl, while others are extremely nasal, which all require time and labour to remedy even imperfectly. He also gives instances of the errors of pronunciation into which the pupils continually fall, and the endeavour to rectify them, and he concludes this portion of his report by saying that "this process is correctly called by the German writers *mechanical speaking*; that much time must necessarily be devoted to it, and that with the greatest efforts, only a defective utterance can be reasonably expected, even under the labours of the most experienced instructors."

Reading on the lips is carried on at the same time with articulation, its difficulties are confessed by the German teachers to be peculiar and great. The object of articulation is to enable the deaf-mute to express his own ideas *to* others, while this is to teach him what is said *by* others, by watching the motions of their lips. How formidable the attempt will appear from considering the following circumstances, mentioned by the German teachers themselves: 1. Many sounds demand positions of the organs so entirely similar to each other, as it respects external observation, that only a *very* practised eye can discover the difference. 2. No peculiar opening of the lips is necessary in the pronunciation of most of the consonants. In such cases it is usually decided by the vowel immediately preceding, and as the lips then conceal, for the most part, the interior of the mouth, the scholar must hence, in respect to many consonants, remain in uncertainty. 3. In the flow of discourse, sounds run so much into one another that only a practised eye can seize hold of the individual parts. 4. The pronunciation of different persons has to the eye so many variations, as sorely to puzzle the deaf and dumb. 5. In connected discourse, many sounds which properly belong to words are lost, which greatly increases the difficulty of understanding by means of sight. For instance, in the sentence *this singer ran nineteen miles*, few persons pronounce so distinctly as to make the *s*, *r*, and *n* twice perceptible, even to the ear, much less to the eye. So great are these difficulties, both singly and in combination, that it is not pretended that deaf-mutes ever become able in ordinary discourse, to make out each word, or even the greater number. All they do is, to make out a few words and guess at the remainder.

In learning to utter sounds himself, the deaf-mute has the aid of two senses, sight and feeling; in learning to read on the lips however, he must trust exclusively to his eye. Hence the need of special exercises in this department. The following are the most noticeable things in the course: 1. At first the teacher speaks as slowly as possible, opens his mouth wide, and distinctly utters every sound. The consequence is, that the pronunciation of many teachers to their scholars is very unnatural, and such as is *never* heard in general society. This probably is one reason of the unnaturalness observable in the pronunciation of the educated deaf-mutes. 2. The most experienced teachers divide the sentences they utter into small groups of words, with pauses between them; sometimes this division goes so far as the making of a pause after every word, or even syllable. 3. Occasion is taken as often as possible, to make speaking a medium of communication. 4. The pupil is generally required to repeat after the teacher, either silently or aloud. 5. Where the pupil fails to catch the word, it is either written in the air or on a slate to aid him. A few teachers use the manual alphabet for this purpose.

With regard to the results obtained in respect to articulation, Mr. Day's report is full and comprehensive, but by no means encouraging. We include a few extracts in his own words: "As would naturally be expected, the teachers are able to make out what their pupils articulate better than any one else. They are acquainted with the particular mistakes of each, and attach a signification to what appear to others only as incoherent sounds." A passage being selected from the Bible, containing no difficult words, but not in the ordinary school exercises, "one of the best scholars who had been five years under instruction, read it twice over, but the teacher was unable to make out any part of it; on the second reading of another passage by a scholar six years under instruction, the teacher repeated the whole." Experiments of this nature were made at other schools, and led to the conclusion, "that the instructors understand their pupils not so much in virtue of the intelligibility of their articulation, as by being accustomed to the circle of words they commonly use." This view is confirmed by the fact which the teachers acknowledge, "that they do not understand the pupils of other schools so well as their own."

A general impression prevails among intelligent Germans that the articulation of the educated deaf and dumb is unintelligible. A bookseller in one of the cities said, "when the deaf and dumb were taught the manual alphabet, it was easy to converse with them, but since that has been abandoned, and we have nothing but articulation, conversation has become very difficult." Mr. Day comes to the three following conclusions on the *intelligibility* of the articulation: 1. A foreigner would find no difficulty in understanding the more common forms of salutation, and a few simple questions and answers. After a few months instruction the pupils are able to say *guten morgen* (good morning) and the like, in a way to be understood. 2. In hearing the oldest class read, he would be able by looking on the book, in the majority of cases, to keep his eye on the place. 3. In hearing the same class read a passage, the book not being in his hand, or should they attempt to speak anything out of the usual course, he would only recognise a few of the more common words.

The *fluency* attained in reading and speaking is in general very little; the articulation is slow and laborious. The reading resembles that of a young child spelling out his words. With regard to *correctness*, words are pronounced in three or four different ways, from failure of memory of the position of the organs, or from want of sufficient power over the organs; the following are given as examples of mistakes in pronunciation: *hehe*, for gegen; *Jadu*, for Jesus; *spree*, for sprach; *nie'and*, for niemand; *frast*, for fragest; *steht*, for stadt; *sspach*, for sprach; *Teibe*, for Weide; *pedete*, for sedete; *Seide*, for Seine; *tint*, for ging. "Of those whose articulation is better than has been described, everywhere constituting exceptions, and everywhere also naturally made prominent when strangers are present, *a large part learned to talk more or less before they became deaf*. Even in cases where the power of hearing is lost at two or three years of age, an idea of articulate sounds is gained, and a flexibility of the vocal organs possessed, which gives a certain advantage in subsequent instruction. But when the child made use of language till four or five years of age, or as sometimes happens, to seven, eight, or even ten, and stranger still, never lost the use of it, the case is a very wide remove from that of ordinary deaf-mutes, and cannot properly be cited without an explanation of the circumstances. It is very common in Germany to refer to a (so-called) deaf-mute instructor in the school at Berlin, named Habermaas, in proof of the degree to which the deaf and dumb can be taught to articulate. That he stood very far above even the best-instructed deaf-mutes, would be sufficiently evident from the frequency with which his ability to converse is referred to. At the same time it alters the case entirely, to learn that not only was he not born deaf, but that he actually lost his hearing at so late a period, that when he entered the school at Berlin, he was still able to talk. In other words, *he had never lost the use of speech*, and as the director of the Berlin Institution, who communicated these facts to me, observed, cannot properly be referred to as an instance of the success of instruction in articulation. 'It is precisely in this manner,' he continued, 'that erroneous ideas are circulated, and unfounded expectations so often cherished, in respect to what can be done for deaf-mutes.'"

There is another class who must be regarded as exceptions in respect to the general results of instruction in articulation, which consists of those who still retain a sufficient degree of hearing, to be made to a considerable extent available. The German teachers acknowledge that the power of distinguishing sounds is of great advantage; although the pupils, by the sense of hearing, may be unable to learn to talk, it insensibly makes the intonation more natural and pleasant, besides affording important assistance in teaching individual sounds.

The results of instruction in reading on the lips was made a separate inquiry. Mr. Day found that pantomimic signs were made use of by the teachers in this branch to a far greater degree than might be expected from the theories they advocate; in conversation even with their most advanced pupils, "they employ a large number of signs for individual words, and not merely substantives and verbs, but even adverbs, prepositions, and conjunctions. . . . . About one-third of the most advanced class, with the aid of the signs employed by the teacher, and the frequent repetition made use of, appear to understand the most of what the instructor says; another third appear to lose a considerable part, while the remainder only seize the most common words, and are obviously much of the time at a loss as to what is going on."

No deaf-mute in Germany would be able to take part in the miscellaneous conversation of a social circle. One of the German teachers informed Mr. Day that on becoming associated with Habermaas as an instructor at Berlin, he early took occasion to say, "You speak too fast, in order for me to understand you; you must speak slowly, and endeavour to make the form of the letters as much as possible on your lips." Partly from the too great rapidity, and partly from the distance also, it would be impossible for a deaf-mute to understand a public speaker. Even Habermaas was unable to understand what was said from the pulpit. The power of reading on the lips, although of course very limited, is available to those who possess it under the following circumstances: First, there must be a sufficient degree of *light*. One of the German teachers apologised for the mistakes made by a pupil by observing that it was twilight, and she could not readily see the motions of the lips. Secondly, it is generally necessary for the deaf-mute to have a full view of the mouth of the person speaking. In some cases, pupils succeed in reading from the lips of the teacher with only a side view. Thirdly, the deaf-mute must be *near* the person speaking; some can read on the lips of their own teachers at the distance of ten and even fifteen feet; usually, however, five feet may be considered the maximum, and many are obliged to be as near as two or three feet. Some teachers are accustomed to make such contortions of the face, in exhibiting the tongue, teeth, and lips, as to render it unpleasant to look at them; others, on the contrary, affirm that these unnatural motions of the mouth are unnecessary, and appear to succeed as well in making themselves understood as the former.

With regard to the influence of articulation on health no statistics had been collected; some teachers contented themselves with observing that they could not say they had seen any injurious consequences, while others admitted that if, in some cases, it had a tendency to strengthen, in others it had a tendency to irritate the lungs, and that no argument in favour of articulation could be drawn from its sanitary effects. Frequently, in witnessing the intense, often amounting to nearly spasmodic, efforts, made by deaf and dumb children in producing vocal sounds, I have felt sure that no parent or physician would be willing to have the lungs of a child or patient, suspected of being inclined to disease, exposed to such a trial. Even the advocates for articulation have their apprehensions, and thus express themselves: "At the outset, caution must be exercised not to cultivate readiness in speaking, at the expense of the health and life of the pupils. . . . . When instruction in articulation is commenced at a later period (than three or four years of age) *great prudence* is necessary that the organs unexercised, and therefore weak, be not too much strained." Of the 92 actual or dismissed pupils in four schools, who are known to have died, 39 perished of consumption. Of the 20 deceased pupils of the Leipzig institution up to 1838, 17 were reported as having died of diseases of the lungs. The distinguished and amiable deaf-mute teacher at Leipzig, Karl Wilhelm Teuscher, who during the fifteen years of his connection with the institution was regarded with pride as a testimony of what could be done for the deaf and dumb, died, it could not be concealed, in consequence of a lung disease, induced chiefly by exertions in instructing his pupils to speak. Was such a fact ever recorded of a teacher who could hear?

Mr. Day selected a number of cases of young men who were engaged in business, in order to ascertain the extent to which articulation was useful to them in the ordinary affairs of life. The first, a compositor in a printing-office, who had been one of the head scholars, could be communicated with *vivâ voce*, in simple words and phrases, but the foreman and journeymen would never think of holding a long conversation with him as with other men; a cabinet-maker who had left the school four years was similarly reported of; a silversmith was a somewhat better example, but he made unpleasant distortions in speaking; another boy, who was met in the street, was conversing with his fellow-apprentice by signs, *not by the voice*; an older sister of the last, was reported of as deriving very little advantage from her articulation; and in the family of these two, conversation was carried on by pantomimic signs. A young man who had been ten years at school could not understand his employer nor the head clerk, nor could they understand him except by writing; and these were the usual reports in all the cases examined. An eminent clergyman observed, "What is truly valuable in the instruction of our deaf and dumb, is the ability to *read* and *write* they acquire. Their ability to speak and read on the lips is trifling, and of very little value."

The only point remaining to be mentioned refers to the comparative difficulties the German and English languages present in the teaching of articulation. It is demonstrable that less favourable results would arise in our language than in some others. The German, the Italian, and the Spanish, are all favourable, being pronounced with slight exceptions as they are written. In languages on the contrary, such as the English and the French, in which the connection between the orthography and the pronunciation is irregular and varying, less assistance of this kind can be derived. In English, many of the letters have so many different sounds, and many too are so silent, that the written word would be a source of perplexity in its pronunciation, which is not the case in the German language. Mr. Day's conclusion is given as follows: *as a regular part of a system of public education, its introduction into our institutions I am persuaded would be a serious misfortune to the cause of deaf and dumb instruction.* The schools visited by Mr. Day were those of Riehen and Zurich, in Switzerland; Tübingen and Gmünd, in Würtemberg; Pforzheim, in Baden; Frankfort on the Maine, Bremen, and Hamburg; Cologne, Münster, Halberstadt, Halle, Weissenfels, Erfurt, and Berlin, in Prussia; Leipsig and Dresden, in Saxony; Weimar and Eisenach, in Weimar; and that of Brunswick. There are several particulars in Mr. Day's report which have not been touched upon here, such as the general knowledge and acquirements of the German pupils compared with others, their religious training, the great expense attending the articulation course of instruction, from the greater number of instructors required, the loss of time involved in a mechanical acquisition, and consequently the less progress made by the pupils in any definite time. All these are subjects which should enter into the consideration of those whose province it is to conduct or direct the education of the deaf and dumb.

The period prescribed for instruction in the public institutions for the deaf and dumb varies in different countries; in few cases is it so short as in England: in nearly all the Continental institutions of celebrity it is considerably longer. With us only five years in most instances are allowed for the education of pupils, who are wholly or partially sustained by the funds contributed for their support. Throughout France, Switzerland, Würtemberg, Sweden, and Poland, the pupils are permitted to continue six years. At the institution of Groningen, at those of Copenhagen and Sleswig, the pupils remain seven or eight years; at Vienna from six to eight years; at Berlin they continue from six to nine years; and at Leipzig for a like period. Should no other modification of the institutions of Great Britain take place with regard to the duration of a pupil's continuance in them, it would be well if some provision were made to enable pupils of superior talent, and those intended for the more liberal arts and trades, to continue under special instruction, to qualify them for their future business, for a longer period than those who need no such preparation. Nearly every boy may learn to make shoes, to hew wood, and to draw water; but it requires a peculiar training to form artists, engravers, clerks, carvers, modellers, and superior mechanics—arts in which there is nothing to prevent the deaf and dumb from excelling.

The subjects on which instruction is imparted must necessarily vary with the length of time given to education. The following plan of a course of instruction cannot be satisfactorily accomplished in less than six years; it is, however, an approximation to what is attempted in some of the British institutions. Still, it must be clear to every one that the educational results attainable in a limited number of years must depend greatly on the age of a pupil at admission. A term of six years, from eight to fourteen, would produce very inferior results to a term from ten to sixteen years of age. We have already noticed the instruments of teaching, and shall proceed to mention the matter of instruction and its division with regard to time, which is assumed to be pretty nearly what is actually accomplished. With regard to a sixth year, were our institutions so modified as to enable the pupils to be kept for such additional time, it would generally be devoted to confirming the pupils in their previous acquirements, to a repetition of subjects of more than common interest, and to special instruction, according to the dispositions and endowments of the pupils, connected with their future destination. In short, it should in every way be made a retrospective year as regards their school acquirements, and prospective as to their future interests.

The subjects for instruction are:—

Language, including nomenclature and syntax.
Writing, as an acquirement and a means towards higher attainments.
Reading, by dactylology and by the eye.
Religion and morals, preceptal and applied.
Geometry and mechanical drawing.
Geography, physical and political.
Arithmetic, elementary and applied.
Drawing, as an art and in connection with design.
History, ancient (from the Old Testament).
History, modern (of England especially, and exemplary biography).
History, natural (animal, vegetable, and mineral kingdoms).
Physics (properties of natural bodies, astronomy, mechanics, chemistry, &c).
Composition (to induce the ready use and application of language).

The *First Year* would be generally devoted to instruction in language by means of natural signs, dactylology, and writing. Instruction in numbers and their combinations by sensible objects, by manual notation [Dactylology], by figures, and by words. Occasional instruction in moral and religious duties by signs.

Second Year.—Instruction in language, continued by the same instruments as in the former year; in arithmetic. Geography commenced with ground-plans of school-room, house, and neighbouring grounds, streets, roads, fields, &c. Lessons on form, introductory to geometry. Moral and religious duties. Composition, commenced by pupils writing down their own observations on facts and occurrences in short sentences. Drawing commenced.

Third Year.—Language continued; the two former years are chiefly given to nomenclature; syntax will now more especially demand attention. Lessons continued in geometry, geography, arithmetic, physics, and composition. Scripture history and drawing continued.

Fourth Year.—Language continued, and especially applied to composition. Direct instruction continued on all the subjects named for the preceding year.

Fifth Year.—In addition to bringing the branches of knowledge commenced to a close, abstract ideas and figurative language; doctrinal religion; the physiology of the human body; the moral and social duties of man, his dispositions and faculties, should be brought under consideration during this year, and continued for as long a period as the pupil remains under instruction. Most of the new subjects here mentioned would necessarily be the work of a sixth year. Those parents who can afford to continue their children as private pupils might have them instructed in every department of a sound English education, and, if they thought proper, qualified for the more liberal arts and professions; for there exists no insurmountable barrier to the acquisition of classical learning, mathematical and scientific attainments, and a knowledge of the modern languages.

After the explanations into which we have entered on the modes and subjects of instruction, no lengthened remarks on the processes seem to be requisite. In teaching substantives the object is pointed out, and the name is written, spelled on the fingers, articulated, or signed, as the medium of communication may be; all these are so many modes for expressing the object referred to. Thus if *man* be the object, it is pointed to, or the word *man* is presented before the eyes of the pupils, or it is spelled by means of the manual alphabet, or it is pronounced, or the beard is touched, and the height of man is indicated. In the same manner other names of objects are conveyed to the pupils, who soon see that a connection exists between *our* conventional signs and objects, as well as between *their* conventional signs and objects. Adjectives are taught in a somewhat similar way; the colours are as easy as any other qualities to introduce pupils to this class of words. A few wafers, all of the same size but of different colours, are good mechanical aids. When the colours are known the teacher will pass on to other adjectives. The nature of the indefinite article is easily exhibited; the definite can only be acquired by practice, in the manner of hearing and speaking children. Verbs of action are easily imitated by signs, and the pupils are prepared to expect that there are words to indicate *action*, as well as *objects*, *number*, and *qualities*. Adverbs, which indicate the manner of an action, naturally follow verbs; to *run quickly*, to *walk quickly*, to *walk slowly*, may, it will be seen, be accurately conveyed by the means employed to bring instruction so immediately under the cognizance of the senses. The possessive, demonstrative, and personal pronouns are exemplified by real facts which come under the observation of the pupil, or which are purposely contrived to arrest his attention, Many of the prepositions and conjunctions can be rendered sensible and intuitive; other particles are taught by diagrams, and by examples produced as occasion requires, and reproduced by the pupils from instances supplied by themselves. The moods and tenses of verbs, and the auxiliary verbs, can only be taught effectually by the events and casualties which bring them into use in ordinary life; these are constantly occurring, and it is the business of the teacher to turn them to account for the improvement of his pupils. Abstract ideas must be traced downwards to those simple ideas from which they originate, as well as from the simple idea upwards; indeed the constant application of analysis or induction, which is continually called forth in conveying instruction as far as may be through a sensible vehicle, renders this office of language more easy than can be conceived by those not accustomed to employ such powerful instruments in the process of education. Figurative expressions, comparisons, similes, metaphors, require a series of progressive lessons, in which language should be employed to illustrate each step from the easiest to the most complicated figures of speech. Examples might be taken from the Scriptures, from fables, allegories, and parables; they should be especially written with a view to utility, and adapted for the explanation of such subjects as occur in any course of education. Though in the plan marked down we have given two years to *nomenclature*, and have not recommended the commencement of *syntax* till the third year, it is not intended that this shall interfere with the pupil's gradual introduction to small sentences expressive of sensible ideas. Indeed the progress in language of a deaf and dumb pupil, to be successful, must be assimilated as nearly as possible to the progress of other children, and he must be continually accustomed to those ordinary exemplifications of language, affirmative, negative, and interrogative, which other children use, and which advance in complexity as their years increase and their minds become enlightened. As the manner and substance of a child's conversations indicate the society in which he has been brought up, and the educational advantages he has received, so will the ordinary remarks and compositions of the deaf and dumb exhibit the benefits they have derived from the means employed to bring them into communion with society, and to elevate their thoughts and understandings to the level of those who labour under no such deprivations.

The art of instructing the deaf and dumb has not been always free from empiricism. Several attempts, some trifling, others heinous, have been made to claim for them intellectual powers and literary attainments to which they have not been entitled; these attempts have for a time been successful, the public has been deceived, and the re-action has been injurious both to the deaf and dumb and their teachers. We trust the days for such deceptions have passed away, and that we live in purer times. Whether the celebrated answers of Massieu, the pupil of Sicard, must be considered as more than liable to imputation, is too difficult a question to decide now. They are so apposite and beautiful that we harbour suspicion with regret. There is no doubt but Massieu possessed powers of mind amounting to genius, but even allowing this, there are few of the instructors of the deaf and dumb of the present day who believe his brilliant definitions and exemplifications to be the genuine productions of his own mind; they know that time has been when, emulating the fame of Massieu, definitions as poetical, compact, and expressive, have been *taught to pupils*; that they have been fully explained, fixed in the mind and memory, and reproduced when required; but they also know that these were not the ideas of the pupils themselves, but of their instructors, though the pupils have had the credit of them. Let us explain how such effects can be produced. The word *eternity* occurs in Massieu's lesson with Sicard. The master illustrates the meaning by drawing a line, and represents it as prolonged at both ends indefinitely; he speaks of this line as representing time past, of which there was no beginning, and time future, of which there shall be no end. Hence, when Massieu gives his answer or definition of eternity, he merely writes, as a less able class-mate might do, "A line which had no beginning and shall have no end," putting the illustration into language, with such others as he had been taught, as, "A day without a yesterday or to-morrow." Analogous was his answer to the question on *time*, "A line that has two ends—a path that begins in the cradle and ends in the grave." The same explanation may be given of the answers on *gratitude*, "the memory of the heart;" a *sense*, "an idea carrier," &c. But the best evidence that teachers have of the process followed is in their own experience. One of them has written thus, "Most of these answers are highly figurative. But the deaf and dumb generally avoid figurative language; their compositions usually are eminently literal; they readily detect resemblances, and frequently employ comparison, but they very rarely personify." The writer of this article has taught 500 deaf and dumb pupils during the last 30 years; but instead of being able to testify, as some writers have put forth, that the deaf and dumb have "a natural aptitude for defining abstract terms," his experience has shown him the reverse. Some of his pupils have gone through a series of abstract nouns in their school-course, but though they have attained a certain amount of skill in defining, illustrating, or exemplifying such words, it was only achieved by dint of severe mental application, by no means common in young people. In his after life Massieu exhibited none of that talent which made his name, with that of Sicard, so famous, although opportunities were not wanting. He conducted an establishment for the deaf and dumb at Lisle for many years, with but little success. He published a nomenclature for the use of the deaf and dumb, of which Degérando says, "It has the double vice of being exuberant; by its multiplicity of words useless to the deaf and dumb, and of being destitute of all logical arrangement;" and he adds that Massieu "could never write the French language with accuracy." He died at Lisle, in 1846.

The most exaggerated notions prevail as to what may be accomplished for the deaf and dumb, in the limited time usually allotted to their education. What is actually done for them in many of our institutions is, however, sufficiently marvellous. Nature does not act so bountifully towards them as is commonly believed, making amends for the lost sense by greatly increased power in the remaining ones, and it is but a popular mistake that the deaf and dumb experience this quickening influence. They are, however, made happy under instruction; they have fellows with whom they can hold converse; they acquire habits of study, care, and industry, which are useful to them in after life; their social, moral, and religious sympathies are awakened; and their minds are informed with knowledge, from which, before the process of instruction commenced, they were shut out. But all this is achieved by the pains-taking labour of the teacher, and he must labour with much patience to ensure that success to which he looks for his reward; for there is no natural gift possessed by these children of silence to ease him of a single burden borne by the ordinary teacher, while he has many doubts and disquietudes which are unknown in the schools for the ordinary population.

DEAF AND DUMB, INSTITUTIONS FOR THE. In 'Le Bienfaiteur,' No. 4 (October, 1853), the Abbé Daras gives a list of 455 establishments, including public institutions, associations, and private schools for the education of the deaf and dumb, with the dates of their foundation. Mr. Day, in his Report (1844), gives a table of 172 institutions in Europe and America, namely: 16 in Great Britain and Ireland; 44 in France; 9 in Italy; 10 in Switzerland; 9 in Austria; 22 in Prussia; 10 in Bavaria; 6 in Würtemberg and Baden; 15 in Saxony, Hanover, and the other German states; 4 in German free cities;

8 in Belgium and Holland; 4 in Denmark, Sweden, and Norway; 2 in Russia and Poland; and 10 in the United States. The actual number of institutions for the deaf and dumb in England, Wales, Scotland, and Ireland, is 20, of each of which we shall give some particulars.

The public establishments for the reception and education of the deaf and dumb of England are situated respectively at London, Birmingham, Manchester, Liverpool, Exeter, Doncaster, Newcastle on Tyne, Bristol, Brighton, and Bath; one for Wales, at Swansea; those of Scotland at Edinburgh, Glasgow, Aberdeen, and Dundee; and those of Ireland at Dublin, Belfast, and Strabane. The asylum at London, situated in the Kent Road, was opened in 1792; it was the first asylum in the kingdom for extending to the indigent deaf and dumb the benefit of education, and, from its establishment to the present time, 2889 pupils have been received and educated there. A bust of the Rev. John Townsend, which is placed in the committee-room, perpetuates his memory as the founder of the institution. Three hundred children from all parts of the kingdom reside in the asylum, which receives ample support from the wealthy; indeed it possesses, besides its annual receipts from subscriptions, donations, and legacies, a funded property of probably not less than 160,000*l.*, by which its permanent income is greatly increased. The instructor of the asylum is the Rev. James W. Watson, a grandson of the late Dr. Watson; he is assisted by male and female teachers. The whole is under the management of a committee. The cost per head of each pupil is under 25*l.* a year; its annual income is little short of 10,000*l.*, more or less, depending in some measure on the amount received each year in legacies; this sum in 1858 was 2150*l.*, the dividends from stock about 5000*l.*, subscriptions 1500*l.*, and from other sources about 1000*l.* was received.

The second institution which came into operation in this kingdom was that of Edinburgh, which was established in 1810, and at first placed under the care of Mr. Braidwood; he was succeeded by Mr. Kinniburgh, since deceased. The number of children at present under instruction is 58. The number of instructors, including the principal, 3, and a sewing mistress. The income is stated by the secretary to be about 700*l.* a-year from subscriptions, and 400*l.* to 500*l.* from payments of pupils. The admission of deaf and dumb children into Donaldson's Hospital has circumscribed the operations of this institution.

The general institution for the deaf and dumb at Edgbaston, near Birmingham, was commenced in 1812. It was formed in consequence of a lecture on the subject which was read by the late Dr. de Lys before the philosophical institution of Birmingham. This gentleman, and Dr. Alexander Blair, late professor of English literature in the university of London, are to be regarded as the first promoters of the institution. It was placed under the superintendence of Mr. Thomas Braidwood, one of the sons of Mr. Braidwood of Hackney. The institution has no provincial limits. It contains 92 pupils; the present master is Mr. Arthur Hopper, who has six assistants. The management of the domestic department is superintended by a matron. For many years this establishment was confined in its means; but its buildings have been recently enlarged, so as to admit of a great increase of pupils, and their sanitary condition has received every improvement that could be introduced. These alterations have involved an outlay exceeding 2000*l.* The funds of the institution arise from subscriptions, donations, legacies, interest of money invested, and payments on behalf of the pupils. Nearly a fourth of the income is derived from annual subscriptions, and more than a fourth from pupils' payments. The cost of each pupil is stated at about 25*l.* annually.

The national institution for the deaf and dumb of Ireland is situated at Claremont, near Dublin. It owes its origin and progress to the strenuous and unwearying exertions of Dr. Charles Orpen. Soon after its commencement in 1816, it was placed under the care of Mr. Joseph Humphreys, who continued to be the principal till 1841, since which time several others have occupied that post. The present master is Mr. E. J. Chidley, formerly an assistant at the London Asylum, Kent Road. About the year 1846, a great change took place in the affairs of the institution. Its original operations included the whole of Ireland; but the extension of that established at Belfast to the entire province of Ulster, deprived the national institution of a certain number of pupils, and of funds derived from that province. The parent institution is now limited in its operations to Leinster, Munster, and Connaught. About the same time a Roman Catholic institution was established in Dublin, which again reduced its number of pupils very considerably. The number reported this year is 56. The accommodation is sufficient for 150 pupils; there are consequently heavy establishment charges, which make the average annual cost for each pupil very high: these, however, are in process of reduction. A few years ago, a deputation from the managing committee visited the principal institutions in the kingdom, with the view of re-modelling their own by introducing such improvements in every department as were found feasible and suited to the altered condition of the establishment.

The Glasgow Institution, formed in 1819, chiefly for the west of Scotland, has had several teachers. Mr. Duncan Anderson, whose persevering efforts have raised it to a high degree of prosperity both as to rank and character, has been its principal for more than thirty years. It contains 82 pupils. It has no fund more permanent than that derived from payments of pupils, donations, legacies and annual subscriptions: the cost per pupil is about 20*l.* annually. Mr. Anderson has four assistants. The domestic arrangements are superintended by the matron. A workmistress has charge of the girls in their sewing and household employments.

The institution at Aberdeen was commenced in 1819; its pupils are chiefly from the north of the Dee, but it has no prescribed limits. About a third of its income arises from subscriptions and donations, a fourth from pupils' payments, and the deficiency is made up from certain funds which are applied to charitable purposes by their trustees. There are 30 pupils, whose cost per annum is about 20*l.* a head.

The school for the deaf and dumb at Manchester was opened in 1823; in 1839 it was removed to a very commodious building, erected by subscription at Old Trafford, on a uniform plan with that for Henshaw's Blind Asylum, the two establishments being in exact architectural correspondence with a chapel between them for the inmates of both and the neighbouring residents. The funds of the institution are derived from subscriptions, about two-thirds; children's payments, one-third. There are 103 pupils whose average cost is 21*l.* each per annum. For the last eighteen years the Manchester Institution has been under the charge of Mr. Patterson, as principal, who is assisted by five junior teachers. In the report of the institution for 1857, the examining committee suggest a novel addition to their institution, namely, an "Infant School," for the reception "at the earliest age practicable of the deaf-mute;" and in the report for 1858, the necessity of extended accommodation for ordinary pupils is urged, and a bazaar proposed as the means of raising the requisite funds for both objects. This bazaar was held in May, 1859, and was so successful that the proposed extensions are now in course of progress. It would perhaps be premature to condemn the project of an infant school for the deaf and dumb, but we must confess we would rather have added a year of gratuitous education to all ordinary pupils whose parents would accept the boon, than have incurred the annual expense of supporting the deaf and dumb at the public charge, probably nine years instead of six.

The Liverpool School owes its origin to Mr. William Comer of that town: it was opened in 1825, and commenced as a day-school, but its original plan has undergone some modifications, and its pupils are of the mixed character of boarders, day-boarders, and day-pupils. Several changes have taken place in its mastership; the present headmaster is Mr. Buxton, formerly an assistant at the London Asylum. This school contains 85 pupils,—33 day-scholars and 52 boarders. Nearly a third of its income is obtained from subscriptions, and rather more than a third from children's payments; the other portion is derived from donations, legacies, and interest of investments. There are three assistant teachers and a sewing mistress.

The West of England Institution for the deaf and dumb was established in 1827. It is situated at Exeter. Its especial object is the "instruction of the deaf and dumb resident in Devon, Cornwall, Dorset, and Somerset." Like the others it is supported by subscriptions, donations, legacies, and by payments on behalf of the children; the payments from pupils amount to about one-third of the expenditure. At present it contains 42 pupils. Its head-master is Dr. Scott, who has three assistants, including the workmistress.

The Yorkshire Institution for the deaf and dumb, situated at Doncaster, was commenced in 1829. Throughout its whole course it has been prosperous. Its funds have gradually increased, and it has been enabled to admit every applicant: and for several years a portion of its income has been set aside towards the establishment of a permanent fund; these accumulations form the capital from which the dividends mentioned below are derived. There are upwards of 100 pupils under instruction, 562 have been received since its establishment. The average cost of each pupil is 20*l.* per annum. The funds are derived from annual subscriptions, about 900*l.*; payments on behalf of pupils, 800*l.*; interest from investments, 150*l.* a year. Donations make up the deficiency. As a rule legacies are funded, but there have been a few exceptions. Mr. Baker, the head-master, has six assistants; the girls, out of school hours, are under the charge of a work-mistress for sewing and domestic work.

The Ulster Institution for the deaf and dumb and blind, situated at Belfast, was first established in 1831; it confines its operations in the collection of funds and the admission of *free* pupils to the province of Ulster; but paying pupils from other districts have occasionally been received. It is sustained by donations, subscriptions, congregational collections, and legacies. In 1858 about 1650*l.* was raised by collecting cards through the medium of district auxiliaries. The entire income exceeds 2000*l.* a year; about 90*l.* was received by pupils' payments in 1858. The ordinary expenses make the cost of each pupil about 18*l.* per annum. The number of deaf and dumb pupils is 94; of blind, 23. The Rev. J. Kinghan is the principal; he has five assistants for the deaf and dumb pupils, and one for the blind. Under the management of the present head-master this institution is assuming a favourable position, and winning from the public a large amount of regard and support.

The Northern Counties Institution for the deaf and dumb, at Newcastle upon Tyne, comprehends the counties of Northumberland, Durham, Cumberland, and Westmoreland, and the town of Berwick upon Tweed. It was established in 1839. It is supported by subscriptions, donations, legacies, and payments from pupils. One-third of its income is derived from subscriptions, and about one half from pupils' payments. The average cost of the pupils during the last five years has been 17*l.* 15*s.* There are 62 pupils in a house calculated for only half that number, but efforts are being made to obtain a suitable and commodious building which promise to be immediately successful; the head-master is Mr. W. Neill, who has three assistant teachers.

The Bristol and Western District Institution for the deaf and dumb was established at Bristol in 1841; its benefits are available to all deaf-mutes residing within the city and county of Bristol, and the adjacent counties of Gloucester, Wilts, Somerset, Hereford, and Monmouth, together with the southern division of the Principality of Wales. Its income from subscriptions and donations is about 400*l.* a year, from children's payments 212*l.*, from Consols 88*l.* The number of pupils is 22. The cost per pupil, with so small a number, and under a heavy rent and other establishment charges, is larger than at the generality of these institutions, being upwards of 30*l.* a year. Mr. Clyne is the head master, he has a female assistant who is deaf and dumb, and a work-mistress has charge of the sewing and domestic occupations of the girls. The expense of this establishment is likely to undergo a considerable diminution, for in March last (1859) the pupils were removed from their rented premises to a house in Park Street, equal to the accommodation of forty pupils, which has been recently purchased. The domestic arrangements are under the charge of a matron, and a ladies' committee gives its services.

The Brighton Institution for the instruction of deaf and dumb children of Sussex, Hampshire, and Kent, was established in 1841. Pupils are received, however, from all parts, priority of admission being given to those residing in the three counties named. It is sustained by annual subscriptions and donations, and by payments from the children. In 1858 two-thirds of the income was from childrens' payments, and one-third from subscriptions and donations. The number of pupils is 78; their annual cost is stated at the small sum of 16*l.* a head. There are eight teachers, four male and four female; two of the latter superintend the instruction of the girls in needlework and domestic duties. The head-master is Mr. W. Sleight, who has been connected with it from the time the first experiments were made, demonstrating the necessity for and the utility of such an institution.

The Institution for the blind and deaf and dumb in Walcot Parade, Bath, was established in 1843; it has no local limits; it is sustained by contributions, pupils' payments, and an annuity of 20*l.* per annum. The subscriptions amount annually to about 360*l.*, pupils' payments to 520*l.*; the number of pupils is 44, including three partially blind, as well as deaf and dumb, and 12 day and Sunday scholars. A Sunday service is conducted by the Rev. Fountain Elwin, the president, which has been found very acceptable, as well as beneficial to a certain number of adults.

The Dundee Institution for the deaf and dumb and blind, is chiefly limited in its operations to Forfarshire; it was established in 1846. It is sustained by voluntary subscriptions, by payments of the full fees and board by parents of some of the pupils, and by partial payments of parents and parishes for others. The average annual cost per head is 18*l.*; there are 40 pupils, and two teachers. Mr. Alexander Drysdale, himself deaf and dumb, is the principal.

The establishment of a Roman Catholic institution for the deaf and dumb in the vicinity of Dublin, was accomplished in 1846; the department for girls is connected with the convent of St. Mary's, Cabra, and was opened in 1847; the number of girls is 80, they are taught by the sisters of St. Mary's convent. The boy's department is under the care of the Christian Brothers of St. Joseph's, Cabra, of the religious order of Saint Dominick; the number of boys under instruction is 87. The cost of each pupil is about 18*l.* per annum. The institution is under high patronage, and is adequately supported. During the year 1857 its annual subscriptions amounted to 767*l.*; donations, 710*l.*; the pupils' payments were 1262*l.*; and bequests amounted to 156*l.*

The Derry and Raphoe Diocesan School for the deaf and dumb, situated at Strabane, was commenced in 1846. It is limited to these united dioceses, including the whole of the county Donegal, and parts of Tyrone and Londonderry. It is sustained by voluntary subscriptions, without any payments from pupils. The 15 children it contains are maintained and educated at a cost of 13*l.* 9*s.* a-head. There is only one instructor, Mr. G. W. Downing.

The Cambrian Institution for the deaf and dumb was established in 1847. It was commenced at Aberystwyth, but a few years after removed to Swansea, at which place a permanent building has been erected, which has been occupied by the pupils about two years. The institution may, however, still be regarded as in its infancy, having had certain difficulties to surmount, together with changes of masters, which have prevented it from accomplishing all its purposes. It has 17 pupils. Its income in 1857-8 was about 600*l.* Mr. A. Melville, formerly an assistant at the Yorkshire institution, has recently been appointed the master.

Donaldson's Hospital, at Edinburgh, was opened in 1850. It is a richly endowed establishment for the maintenance and education of 150 boys and as many girls, with a preference for all of the name of Donaldson and Marshall. The governors have devoted a portion of the institution for the education and maintenance of deaf and dumb children. There are 42 deaf and dumb boys and 28 girls in this department. The number of instructors occupied in this special work is four, three males and one female. The pupils are admitted between the ages of seven and nine, and remain till they are fourteen. The principal is Mr. Angus McDiarmid. Whether the experiment here in progress, of bringing up deaf mutes with hearing and speaking children, will prove beneficial in any respect to the former, has yet to be seen. Some hopes were once entertained that results might ensue favourable to the acquisition of our vernacular idioms, always a work of some difficulty to the deaf and dumb.

All these institutions are under the direction of committees chosen from the subscribers residing in or near the towns where they are situated. These committees appoint masters and other officers not chosen at the annual meetings; they establish the general rules of the institutions which they control, but they do not interfere with the course of instruction. One or more examinations of the pupils take place in the course of each year, which the subscribers and the public generally are invited to attend.

Industrial occupations for both boys and girls are a feature in most of these institutions, though trades, as a future means of obtaining a livelihood, are not taught; the limited time which the deaf and dumb have for instruction in language and knowledge forbids the appropriation of any portion of it to what may be better acquired under a master and during apprenticeship. It must be borne in mind that ordinary apprentices have fourteen or fifteen years in which to learn the language, ways, and customs of the world in which they live, while the deaf and dumb have to acquire all this by direct teaching during their school years to enable them to compete with others in the acquisition of a trade; in order to make the most of their school life, long hours of teaching generally prevail, and the industrial employments and other exercises which health demands fill up their days. Large gardens are attached to many of the institutions, in which the boys obtain a certain amount of healthful exercise by their labour; in two of them printing is taught to some of the elder children, basket-making in one, farm-work at another; in all, the girls are taught household work, and sewing; and in many, the boys perform those offices which fall to men-servants in large establishments. Several of the institutions grant premiums towards the apprentice fees of both boys and girls on leaving school, provided the business and the master or mistress are approved of. In most of the institutions there are three classes of pupils; the most numerous are the poor, who are either instructed gratuitously, or who pay a small sum, varying from 2*s.* 6*d.* to 3*s.* 6*d.* per week. These sums are paid by the parents or friends of the children, or by the parishes to which they belong. In the latter case, it has often been found a difficulty to convince overseers of the policy of educating their indigent deaf and dumb, and thus restoring them to society; but under the operation of the new Poor Law, the difficulty is in some measure provided for; permission being there given for the advance of sums for the "deaf and dumb and blind." It must, however, be stated, that this permissive clause is not sufficient to bring the deaf and dumb of the poor and pauper class under instruction, and the sooner the required payments are made compulsory the better it will be for the deaf and dumb and the community. The second class of pupils received into our institutions are those whose parents can afford to pay their expenses, so that no burden is in such cases imposed on the funds subscribed for charitable purposes. The payment is generally 20*l.*; this being about the average expense of pupils in the provincial institutions. The third class of pupils are those whose friends can afford to pay a large sum for their education. The number of such pupils being very limited, the masters of institutions generally have a proportion of the income arising from this source assigned to them.

The establishments for the deaf and dumb have become doubled in number during the last thirty years, and considerably more than double the number of children of this class have come under instruction during the same period. Most of the important institutions are now full, several have been enlarged recently, and others are contemplating further extensions. In one only has the number materially diminished, namely, the National Institution of Dublin, while its decrease is more than made up by the extension of the Ulster Institution, and the Roman Catholic establishment at Cabra. The number of pupils under instruction in the United Kingdom is now 1550, against 780 when the article in the 'Penny Cyclopædia' was published twenty-two years ago. And what are the Results of this extended movement and of the education of this class? We are enabled to answer this question thoroughly with regard to one institution, at which it is the custom at intervals of a few years to make inquiries respecting all former pupils on the following points:—

1. In what occupation has A. B. been engaged since *he* left school?
2. Is it found that *he* has acquired that business with the same facility, or nearly so, as those who hear and speak?
3. Has *his* conduct been generally approved of?
4. Note any particulars respecting A. B. which are likely to be interesting to the committee.

These inquiries were renewed during the present year, they were addressed to clergymen of parishes or other ministers of religion, to employers, and to parents, and from the detailed answers, which are all published, the following analysis has been made. Of the 534 who had been received into the institution, 480 had left school, and are thus accounted for: of 296 (174 boys and 122 girls) there are formal or informal returns; 32 were deficient in intellect though generally improved, 27 died during education, or before acquiring trades, 4 were removed from delicate health, 13 left school, chiefly from removal of parents, during education, 11 were private pupils, who returned to their friends, 47 have made no return to the inquiries instituted; 174 of the 296 were boys, who have been put to the following trades: 32 shoemakers, boot-closers, cordwainers, 28 labourers, or farm servants, 16 tailors, 12 employed in mills, factories and clothing trades, 10 cutlery, and Sheffield trades, 9 joiners, cabinet makers, carvers, turners, French polishers, 8 letter-press printers, or compositors, 8 engravers, or wood-engravers, 7 engineers, mechanics, moulders, pattern makers, 5 farmers, 4 lithographers, or lithographic printers, 4 pattern designers, 4 quarrymen, 3 bookbinders, 3 gardeners, 2 clerks, 2 painters and decorators, 2 bakers, 2 artists, 2 nailmakers, 11 at sundry occupations, as under; namely, 1 assistant at institution, 1 stenciller, 1 hawker, 1 brickmaker, 1 modeller, 1 type-founder, 1 collier, 1 miller, 1 watchmaker, 1 porter, and 1 hairdresser.

The 122 girls have been brought up to the following employments: 44 dressmakers; 31 assist in domestic duties, sewing, &c., at home; 17 servants or laundresses; 14 milliners, dress and bonnet makers; 10 burlers, reelers, winders, weavers; 2 boot and shoe-binders; 4 sundries (tailoress, cap-maker, lacemender), &c. Of the 296 included in the above summary, we have full and satisfactorily attested returns on 217.

The next important object of this inquiry was to ascertain the facility with which the pupils who had been put to trades acquired them, in comparison with young people not deaf and dumb. Of the 132 boys, it is found that 80 acquired their business as well as others, 28 nearly as well as others, 9 more readily than those not deaf and dumb, and 10 not so well as those who hear and speak; 5 cases are doubtful. Of the girls it is ascertained that 55 acquired their business as well as others, 21 nearly as well, 5 more readily than others, 3 not so well, 1 case doubtful. The summary of the whole 217 will stand as under: 135 acquired their business as well as others, 49 nearly as well, 14 more readily than young people generally, 13 not so well as those who hear and speak, 6 doubtful cases.

A conclusion very favourable to the pupils may therefore be formed; they are, to say the least, equal to young people endowed with all their faculties; for if only 13 out of 217 failed to a certain extent in acquiring their business, it may be fairly inferred that an equal number of failures would have occurred out of 217 persons with all the advantages of speech and hearing; and it must be borne in mind that in nearly all cases these children were under the disadvantage (referred to by some of their employers) of associating with parties not accustomed to the deaf and dumb, who found it difficult to explain their precise meaning, or give directions with accuracy. On the other hand, several of the employers are so thoroughly satisfied, that they express their willingness to take other pupils from the institution. Enough has been ascertained with regard to the facility of the pupils in acquiring trades to force this conclusion on the public mind, namely,

That the deaf and dumb, as a body, acquire trades quite as well as those who hear and speak.

The part of the inquiry on which the greatest anxiety has been felt regarded the character and conduct of the pupils after quitting the institution. A deaf and dumb young person attracts attention which others do not; and while one party by over-indulgence would manifest unusual and uncalled-for kindness towards such a person when thrown on the world, another would heartlessly lead him astray, by indulging him in propensities which require to be checked.

On this point, knowing there is a liability to error, it may be observed that a deaf and dumb apprentice ought to be treated precisely like ordinary apprentices; in his business he should be *shown* what others are *told* of operations and their effects, and this *showing* will generally repay the little extra trouble required, in the accuracy of its results, compared with *telling* in ordinary cases. He should neither be treated more harshly nor more indulgently than others, and his general treatment should manifest to him that he is considered morally and mentally responsible in the same sense as others.

With reference to the reports received as to the conduct and character of the boys: 98 are reported of favourably, 18 very favourably, 6 have given cause of complaint, 3 have misconducted themselves, and in 7 cases the reports are doubtful. Of the girls: 55 are reported of favourably, 21 very favourably, 6 have given cause of complaint, 3 have misconducted themselves. So that the summary of the 217 will appear thus: 153 are reported of favourably, 39 very favourably, 12 have given occasional cause for complaint, 6 have behaved very ill, 7 doubtful.

It is matter for congratulation, that out of 217 cases there are only *six* of immoral conduct, while the large proportion are well reported of. Of the slight causes of complaint, several of them are cases of *obstinacy*, but the question may arise whether the same proportion would not have occurred in ordinary cases—whether out of 217 apprentices, from any class, *so many* would have been reported of favourably, and *so few* unfavourably?

Although the above statement refers to only one institution, there is every reason to believe that reports equally favourable might be obtained from many others; as the result of a direct inquiry made at all the institutions on this point, it may be inferred that all the pupils, with the exception of about 5 or 6 per cent., conduct themselves creditably in after life. Such results show the public that their expenditure in support of institutions for the deaf and dumb is well repaid, and lead to the question why those of general education are less satisfactory. The system of boarding the children must be credited with a certain measure of these favourable effects; the children are separated from the evil influences of towns, and placed under the charge of chosen assistants, who superintend them both in and out of school for five or six years, and during this time habits of regularity, propriety, industry, and attention to moral and social duties are formed, which must assist materially in influencing their future lives. With children not labouring under their privation, a similar system would doubtless be productive of equally good results; and as less time would be required in school, the industrial element might be added, and time applied to productive arts which would reduce the cost of education to such an amount as a small tradesman or a skilled mechanic might pay without inconvenience.

Although the instruction and education of the deaf and dumb have become more general, by the extension of the older, and the establishment of new institutions, there is some doubt whether the quality of the instruction has materially improved. Thirty years ago, a danger was felt that much of the practical application of the art would be lost, for no means had been taken to give permanence to any series of lessons by means of the press. The different teachers experimented, and carried out what seemed right in their own eyes; they had the theories of those who had lived before them, but no series of lessons reduced to order, and no aids for those who were inclined to take up the work as a profession. In the year 1841 two of the teachers resolved to print their early lessons, not only for the use of their own pupils, but also to give form and substance to their manuscripts, and to establish a beaten track which others might widen and improve, and from which they might deviate into better paths. A copy of this confessedly imperfect work was sent to every institution in the kingdom. Since then some attempts have been made by other instructors to supply a series of lessons, but none have met with general acceptance. To this work teachers should at once apply themselves. A concentrated effort can alone be successful. None of the British teachers agree in considering the work published by Dr. Peet of New York as meeting their view of what is required, while there are several individuals among them fully capable of projecting and carrying out a preparatory course of instruction very superior to it. Nearly every teacher will agree with the writer of this article that no series of lessons hitherto published in England meets the views they entertain of what such a series should be, and it is to be hoped their attention, as a body, will soon be directed to this their most manifest want, and to the means of supplying it.

In the year 1857, the committee of the London asylum published an 'Illustrated Vocabulary for the Deaf and Dumb.' This work contains 4000 woodcuts of objects, with their names arranged *alphabetically;* the engravings are generally well-executed, but the arrangement is as bad as could be adopted. One-half the expense incurred, with a suitable distribution of lesson-matter, would have given our institutions a book of immense practical value to them. In its present form, it is a capital family picture-book, without reference to the deaf and dumb, but only where price is no object; to the latter it is of little value, except as a dictionary or book of reference. Every teacher of the deaf and dumb is ready to contradict the statement put forth, that it is "eminently adapted to assist teachers in their endeavours to impart to the deaf-mute a knowledge of language through the faculty of sight, and to enable him to use words as the expression of his thoughts, and as the means of communication with his fellow beings." The woodcuts, however, might be rendered very serviceable under a different arrangement, with a comparatively small number of additional ones. If one portion of the work were made quite elementary, consisting of a certain number of easy nouns, printed on one side or on both, and purchasable in either form, many copies of such portion would be required in every institution, for beginners spoil many copies of their first books or lessons. This portion might be followed by successive ones; as examples of the singular and plural, of adjectives, of prepositions, of verbs, of adverbs; and other grammatical forms of language might be represented with little more labour than re-arrangement. The republication of the work thus disposed, in parts, would be a boon to both teachers and pupils, and really assist deaf-mutes in obtaining some "knowledge of language through the faculty of sight." A wealthy establishment might undertake this task, and the committee of the London asylum, having the charge of this 'Illustrated Vocabulary' bequeathed to them by their late principal, would thus make it widely available to the deaf and dumb of this and other countries, for its use should by no means be confined to the English language; the French, the German, and other continental schools, would doubtless avail themselves of it, if published in a form acceptable to them. For want of such an arrangement as is here suggested, and in order to make the present work available, several institutions have used *two* copies to make *one*, by cutting out the whole of the pictures, and remounting them in a progressive and classified form. *Abacus, abbess, abbey, abbot, abyss, acacia, acanthus, acclivity*, and *accountant*, are certainly not the first words a teacher would bring under the notice of his deaf and dumb pupils; instead of them he would select the names of common objects, known to the children, short, and easy of imitation in writing, such as *hat, nut, pin, pen, cat*, &c. It is to be hoped that a future edition of the work will be published under some such progressive arrangement, and that in other respects it will be freed from the grave faults ascribed by Degerando to Massieu's 'Nomenclature,' which criticism applies very forcibly to it in its present form.

Annual subscriptions, together with payments on behalf of pupils, effect much towards the support of this class of institutions, and the deficiencies are generally supplied by donations and legacies. Still the idea is gaining ground that as government aid is so freely rendered to all educational purposes for which it is sought, its application to our deaf and dumb establishments would be desirable, and would not be refused. The form in which such grants should be asked is a question for consideration, perhaps that of payments to assistant-masters would be one eligible mode of help. If each provincial institution could receive, according to its magnitude, from 50*l*. to 100*l*. a year in augmentation of the salaries of assistant-masters, a better payment to this class of teachers would be secured, and a succession of teachers might thus be relied on. There are no prizes in this department of education, the few chances of advancement to head-masterships are not sufficient to tempt young men to remain attached to institutions when so many openings for them occur in commercial houses, in joint-stock companies, and in the public service. Many good teachers would be retained in institutions, who at present seek places of greater emolument, if they could see the prospect of a second-mastership with such an addition to their salaries as would insure them 80*l*. or 100*l*. a year, besides board and lodging. Another boon the committee of council might confer on these institutions is the privilege of grants of books, maps, pictures, and diagrams, or the purchase of the same as by ordinary schools. Grants in aid of buildings, and extensions of existing establishments are also needed in many localities, but not so much for the purpose of additional institutions, as to render those in operation more efficient. Schools of fewer than 50 pupils do not carry on the work economically, and it is not desirable to multiply such schools. But it must be borne in mind that one-eighth of the deaf and dumb population should be provided for. It has been shown that Great Britain and Ireland contain 17,300 deaf and dumb persons; that 1550 only are under instruction, while 2175 is the due proportion; the deficiency therefore amounts to 625, yet to be brought into our schools.

These grants would probably not be conceded unless accompanied by government inspection; to this we apprehend no objection would be raised either by committees or by principals of institutions, provided the inspector was himself a teacher of the deaf and dumb. No other inspector could go through the examinations required satisfactorily to all parties, nor make due allowances for the difficulties attendant on such a course of teaching; each child would have to be examined in every branch of instruction, and from a week to a month, according to the number of pupils, would be required in the examination of each institution, and reporting thereon.

Besides the ordinary public institutions for the education of the deaf and dumb, another class has arisen in London, Manchester, and Leeds during recent years, while their especial object is met in other localities also, as at Birmingham, Glasgow, Belfast, and Bath. A description of one of them will show the operation of all, and that of London may be taken as their type, premising, that in the metropolis some objects are pursued which are not called for in the provinces. The chief feature of the association in aid of the deaf and dumb, in Bedford Row, London, is to supplement the work commenced in ordinary schools. The deaf and dumb are certainly more isolated than any ordinary class of persons, while they are naturally inclined to seek each other's society. By assembling them for week-day lectures, and Sunday instruction, the powers of mind of adults, especially those of the inferior class in intellect, are prevented from collapsing, or falling into a state of normal weakness. When they meet on Sundays the prayers of the church of England are read by signs, and plain explanations of some portion of the Liturgy, and of a passage from the Bible, are given, so that they can understand such instructions. Another important sphere of usefulness is home-visiting, by which the missionary employed becomes acquainted with their personal habits and wants; work is procured for the unemployed, and this part of the operations of the association has been attended with considerable success, for during the last three years regular employment has been obtained for about *forty*. Pecuniary loans have been advanced to about *sixty*, in times of temporary want or distress, and though on some occasions these loans become gifts, there is generally much good feeling exhibited in the repayment of such advances when the recipients are again earning wages. Occasional tea-meetings are held, and lectures are given on literary and scientific subjects in which the members evince much interest; in many cases drunken habits have been superseded by temperance, and steady industry has taken the place of an idle life. These are no trifling effects to produce, and they are all of that tendency which must increase the self-respect and self-dependence of the class thus benefited. At Manchester and Leeds several of the above objects are also carried out; at Glasgow, Birmingham, Bath, &c., Sunday services are held for the former pupils of those localities.

Within the last few years the literature which concerns the deaf and dumb, has received a valuable accession by the publication of two works in the French language, one by the Abbé Carton, director of the institution for the deaf and dumb, of Bruges; and the other by M. Valade-Gabel, honorary director of the Imperial institution for the deaf and dumb, at Bordeaux. We must explain how these two works originated. In 1833 the central society for the education and assistance of the deaf and dumb of Paris, declared their intention to award a prize for a work on the education of the deaf and dumb which should be applicable to home instruction and to common schools. In answer to it only two competitors appeared, while it was considered that neither of the works fulfilled the conditions of the offer, and no award was made. In 1855 the proposal was renewed, and produced eighteen competitors, to one of these, the work by the Abbé Carton, the prize was adjudged; another by M. Valade-Gabel, was considered entitled to very high distinction: these are the two works before us, four others were honourably mentioned.

The Abbé Carton's is distinguished by much simplicity and great clearness; it is not merely instructive, but it is also attractive. In an interesting and somewhat dramatic story the processes of teaching are unfolded in logical sequence, and connected with each other throughout the work. Petit Paul, the hero of the process, is the deaf and dumb child of the mayor of a commune in France, and a great favourite with M. Thomas, the modest and enlightened teacher of a common school, who had been the teacher of most of the fathers and mothers of the young generation, and who was universally esteemed for his useful life, as well as for his personal merits. A professor of the art of instructing the deaf and dumb takes especial pains to persuade M. Thomas, against his own will, that it is his duty to undertake the instruction of little Paul; that such a work would not only be easy but also pleasant. He undertakes the task, and step by step his efforts are conducted to a successful issue under the guidance of the professor. The work abounds in philosophical interest, it is written with great elegance of style, and displays an accurate knowledge of the difficulties to be surmounted, but it does little more than trace the outline of the plan to be pursued, and it would require a more practical development of every step taken to make it a useful guide to French parents and schoolmasters.

The work of M. Valade-Gabel enters largely upon the whole theory and practice of instructing deaf-mutes, and is one of the most able, and at the same time, interesting works which a teacher, whether of the deaf and dumb, or of an ordinary school could study. It will be suggestive to both, it may make a teacher of a common school, who enters into its spirit, forsake his vocation to become a teacher of the deaf and dumb, but it can never make him fulfil the scholastic duties which would devolve upon him with both these classes of pupils. The work comprises a series of practical lessons superior to any others we have seen in the French language, but we do not consider that either this work or the Abbé Carton's fulfils the proposal of the central society, nor do we consider that object an attainable one. The Abbé Carton's volume is entitled to high commendation as an attempt to popularise the instruction of the deaf and dumb, and it will serve to show parents and others how difficult is the art in practice, while it may encourage a few who have leisure and inclination, to prepare their children's minds for the professor. M. Valade-Gabel's work is a truly philosophical treatise brought down to the comprehension of common minds, but not to the practice of common schools.

On this subject we must refer again to Mr. Day's report on the German schools. He found some common schools in which the instruction of the deaf and dumb is carried on with that of children in the possession of all their senses. This theory was advanced in England about thirty-five years ago by the friends of a deaf and dumb person named Arrowsmith. The results in Germany are far from flattering; it was found that two years of separate preparatory instruction were first necessary, and then two hours of additional instruction daily, and the result was, that the deaf and dumb scholars were taught with the other pupils only in a few mechanical exercises; such as arithmetic, writing, and copying from dictation. There is another class of schools for deaf-mutes in some of the German States, connected with seminaries for the education of teachers for the common schools, but in the operation of this plan two very important preliminaries are overlooked: 1st, that long experience and peculiar qualifications are necessary to form an accomplished teacher of the deaf and dumb; and 2ndly, that in order to succeed, the teacher's whole attention must be devoted to the work. Another attempt to popularise the education of the deaf and dumb in Prussia is the advocacy of day-schools instead of boarding-schools; it is contended that on the German system of teaching articulation and reading on the lips, any newly-acquired power of speaking may be put into immediate practice, and that thus their facilities of utterance would be increased and improved, as well as their power of reading from the lips of others. But this is mere theory, for which present results should not be compromised; by its adoption none of the advantages looked for would be realised, while the deaf-mutes, as a class, would lose that careful training, watchfulness, and moral guidance which a residence in a boarding institution confers. Mr. Day mentions that some of the German schools are designed for the deaf and dumb and the blind. It is said that this unnatural union is rendered necessary only from economical reasons; this is scarcely a sufficient excuse for either these schools or those in the United Kingdom, in which the two classes are received. We doubt if it is a wise economy, for there is no common union either in the modes of instruction or in the other processes of education.

Institutions for the deaf and dumb have been established for rather more than forty years in America, and are fast extending to all the States of the Union. That at Hartford, Connecticut, was commenced in 1817; New York in 1818; Philadelphia, 1821; Danville, Kentucky, 1822; Columbus, Ohio, 1826; Staunton, Virginia, 1839; Indianapolis, Indiana, 1843; Knoxville, Tennessee, 1844; Raleigh, North Carolina, 1845; Jacksonville, Illinois, 1849; in South Carolina, 1849; Louisiana, 1852; Wisconsin, 1851; Michigan, 1854; there are also institutions in Iowa and Missouri. We have not space for particulars respecting these institutions; in the aggregate they educate upwards of 1600 pupils; they are carried on in a vigorous spirit by zealous and intelligent teachers, and they are fulfilling their purposes as well as those in our own country; though, in some respects, they are carried on under disadvantages which are unknown to the schools in the British Isles.

The Canadian government established an institution for the deaf and dumb at Montreal a few years ago; it is understood to be flourishing, but we have been unable to obtain any particulars as to its extent and progress. In the year 1856 a small institution was commenced at Halifax, Nova Scotia, which has recently increased in extent, and received much public favour; according to the Annual Report (1859), it contains twenty-seven pupils, several of whom are adults.

The advantages which have resulted to the community from the education of deaf-mutes have been large and important. The class itself, as an item of this public good, is brought from the normal condition described in the earlier part of this article into that of intelligent moral beings, awakened to the tenure by which human life and citizenship are held, and to the hopes which religion inspires. In the every-day business of life we find a fair proportion of deaf-mutes occupied in workshops, counting-houses, studios, and various other offices, who by industry and trained skill support themselves creditably, and whose general good conduct entitles them to respect. Without instruction these persons could not have been producers, but would generally have been a burden on the industrious classes. The art and science of primary education have also been gainers from the experience acquired in simplifying knowledge for the instruction of the deaf and dumb, whose teachers work upon the ignorance of their pupils rather than on any supposed acquirements. Children who have in the first instance to obtain their knowledge of language by single words, by short sentences, by visible objects or their representations, require the aid of black-boards, diagrams, pictures, plans, maps, models, collections of natural and artificial objects, and such other illustrations as the inventive talent of their teachers can suggest. The greater part of these accessories to instruction were employed in our deaf and dumb institutions for many years before they were recognised as legitimate aids by ordinary teachers. The time has arrived when they are generally adopted, and by their means, simplified and improved modes of instruction have arisen in the majority of schools.

DEAFNESS, the sense of hearing diminished or abolished. Deafness is either congenital or acquired. When congenital, it arises from an original malformation of the ear, and is then always accompanied with dumbness. When acquired, it arises from a variety of diseases affecting different parts of the complex apparatus connected with the sense of hearing. Some parts of this apparatus are placed beyond the reach of examination, and the function of other parts is but imperfectly known: so that it is often difficult to ascertain the exact seat of the disease, still more difficult to ascertain the exact nature of the disease, and even when this is discovered, more difficult than all to apply an effectual remedy. Hence the study and treatment of deafness are attended with peculiar difficulties; yet the subject has by no means engaged such a share of the attention of the scientific surgeon and physician as its importance deserves.

Deafness may arise from disease of the organ of hearing, or from disease of the brain. The organ of hearing consists of two parts, that destined to collect and transmit sound to the auditory nerve, and that composed essentially of a peculiar arrangement of the sentient extremity of the auditory nerve destined to receive sound and to transmit the impressions to the brain.

That part of the apparatus whose office it is to collect sound is termed the auricle, or the external ear—the ear commonly so called. [EAR; NAT. HIST. DIV.] From the auricle proceeds a narrow winding passage, termed the external auditory passage (*meatus auditorius externus*), which is closed at its farthest extremity by a membrane called the *membrana tympani*, or the drum of the ear. Beyond the membrana tympani is the cavity of the tympanum, which is a chamber of air, containing a curious and complex apparatus, put in motion by the vibrations of the air that produce sound. These vibrations are communicated to the internal apparatus by the membrana tympani, or drum of the ear, and, variously modified by that apparatus, and communicated to the air in the chamber of the tympanum, are conveyed to the internal organ, or the ear properly so called. Besides all this there is the passage called the Eustachian tube, which leads from the throat to the cavity of the tympanum. All these parts of the ear are subject to various diseases, any one of which is capable of impairing in a greater or less degree the sense of hearing, or of producing deafness.

Any considerable malformation of the auricle, or external ear, whose office it is to collect the vibrations of the air that produce sound, is found to occasion a greater or less degree of deafness. But the external auditory passage is lined by a vascular and highly sentient membrane, studded with organs of secretion, by which are elaborated the cerumen, or wax, with which the passage is kept in a state of moisture, and by which it is defended from the entrance of external bodies. A certain quantity and a certain quality of this secretion are indispensable to a sound condition of the function of hearing. If the secretion be diminished or suppressed, the hearing becomes extremely imperfect; if it be increased and thickened, the hearing may become altogether abolished. The quantity and quality of this secretion may be changed, in either of these modes, by many diseases; by inflammation, for example, induced by the application of cold and other causes. Accordingly, a vitiated state of the secretion of the wax, which may be accumulated in such a degree as completely to block up the passage, and so to prevent the transmission of sound to the internal ear, is among one of the most common causes of deafness. But inflammation may pass into ulceration; purulent matter may form, collect, and completely obstruct the transmission of sound. Moreover, morbid growths, as polypi, may spring from the lining membrane of the meatus, and plug up the passage. In these different modes there may be a complete obliteration of the auditory passage. This obliteration of the auditory passage is ordinarily attended with the total abolition of the sense of hearing; yet cases are on record in which the canal has been reduced to less than a line in diameter, and in which its walls at different points have even touched, without a great degree of deafness having resulted. In these cases, instead of deafness, there has been a constant noise or buzzing in the ear. Occasionally, though very rarely, there is the opposite state of the auditory passage: it is preternaturally enlarged; in one case it was so much enlarged, that the ring-finger could easily penetrate to the bottom of the canal. Deafness equally resulted from this enlargement of the auditory passage as from its obliteration.

The diseases of the auditory passage may be communicated to the membrana tympani, which may be inflamed, thickened, ulcerated, and rendered wholly incapable of performing the office of transmitting sound. It has been observed to acquire a thickness as great as that of the sclerotic coat of the eye, by a successive deposition of adventitious membranous layers. It is then of a yellowish colour, and quite opaque. Deafness often coincides with this altered condition of the membrana tympani; but it is doubtful whether, if this be the sole affection, it be capable of abolishing the sense of hearing.

The membrane which lines the chamber of the tympanum may partake of the diseases of the parts of the auditory apparatus which are external to it, or it may itself be the primary seat of disease. It may become inflamed and thickened, in consequence of which the capacity of the chamber for containing air must be proportionally diminished. The fluid commonly secreted by its membrane may be increased in quantity and vitiated in quality, and this increased and vitiated liquid may occasion deafness by the exclusion of air from the chamber. Such an altered secretion occurs chiefly in children and young persons, whose mucous secretions in general are easily deranged. This accumulation may take place without any pain in the ear, without any discharge of fluid from the ear, and without any appreciable lesion of the auditory passage. It may be suspected to be the cause of deafness when the sense of hearing varies materially at different periods of the day; when the deafness is greatest in the morning, and is suddenly and manifestly increased by a damp day, or by exposure to a cold and humid atmosphere. There may also be an accumulation of pus or of blood in the chamber of the tympanum. Pus may be suspected to be accumulated in the tympanum when deafness follows severe pain in the internal ear, attended with other signs of inflammation; and when inflammation and ulceration of the auditory passage are either absent or exist only in a slight degree. Blood may be suspected to be contained in the chamber when deafness follows a severe blow on the head in the neighbourhood of the ear, or a fall, or any cause by which a preternatural quantity of blood is determined to the head. Whether the cavity of the tympanum be obliterated by an increased secretion of the fluid which moistens its walls, or by an accumulation of pus, or of blood, the effused matter is often spontaneously removed by absorption, and the sense of hearing gradually returns as the process of absorption goes on.

One of the conditions essential to the sense of hearing is a free passage of air to the chamber of the tympanum through the Eustachian tube. But the diameter of this tube may be diminished or wholly obliterated by an accumulation of the mucus which moistens its internal surface, by the thickening of its lining membrane, and by the adhesion of this membrane at different points. The entrance of air into the Eustachian tube may also be obstructed by various diseases of the throat, as inflammation attacking the soft palate and the tonsils, the consequent enlargement of the tonsils, which may cover and completely close the opening of the Eustachian tube. The inflammation may also spread from the throat into the Eustachian tube; hence the pain in the ear and the deafness which so often accompany severe sore throat.

The internal ear, or that part of the auditory apparatus in which the impression of sound is received, the true and proper ear is, without doubt, subject to its own diseases; and it is probable that a very slight change in this delicate structure is sufficient to occasion deafness. But this organ is placed so far beyond the reach of examination, and the function of its different parts is so little understood, that its morbid changes, as the causes of deafness, are alike obscure during life, and difficult to be appreciated by inspection after death. The same is true of the diseases of the nerve which transmits the impression from the internal organ of hearing to the brain, and of the diseases of the brain itself. We know that it is indispensable to the sense of hearing that this part of the auditory nerve be sound, and that that portion of the brain with which the auditory nerve is in immediate communication be sound; we know that the auditory nerve and the brain are both subject to numerous diseases which impair or abolish their functions. The substance of the nerve may be diseased, or a tumour may press upon it in some part of its course to the brain; the brain may be diseased, inflamed, softened, hardened, oppressed by the effusion of water, lymph, pus, blood, or by the growth of tumours in its substance, occasioning general diseases, the most severe to which the body is subject, as phrenitis, hydrocephalus, epilepsy, apoplexy, &c. Among the local morbid phenomena produced by these diseases, deafness is always one. Often also this malady immediately follows repelled cutaneous eruptions and retrocedent gout, and it is the frequent concomitant of fever. In all these cases deafness is the consequence either of disease of the brain, or of disordered secretions of the auditory apparatus, or of both conjoined; and the hearing always returns as these diseases diminish and disappear.

When deafness arises from inflammation of the auditory passage, the deafness can be cured only by the removal of the inflammation, which must be treated according to the principles proper for the treatment of inflammation in any other part of the body. When deafness results from a disordered action of the follicles which secrete the wax, it is often removed by introducing into the auditory passage, night and morning, a dossil of cotton, containing some stimulating substance, as camphor, ammonia, or alcohol, suspended in almond-oil. When the auditory passage is loaded with hardened wax, the ear should be syringed night and morning with warm milk and water, or soap and water. When polypi grow from the lining membrane of the passage, they must be removed by a surgical operation, and the proper precautions taken to prevent, or the proper remedies employed to remove, inflammation. When there flows from the passage an acrid or fetid discharge, the ear should be cautiously syringed night and morning, and counter-irritation kept up by repeated blisters behind the ear, or by a perpetual blister, caused by daily dressing the vesicated surface with unguentum lyttæ. When the deafness arises from a diminished secretion of wax, good effects have often been experienced by the employment of galvanism, which is found not only to occasion a grateful warmth in the meatus, but also considerably to augment the secretion of wax. When deafness arises from inflammation of the membrane which lines the chamber of the tympanum, and from the consequent thickening of the membrane, or the effusion of fluid into the cavity, the most effectual remedies are blisters behind the ears and active purgative medicines. When closure of the Eustachian tube is the cause of deafness, the imperfection of hearing is often immediately removed by perforating the membrana tympani, this operation immediately establishing a free communication of air to and from the tympanum. When deafness is the consequence of disease of the auditory nerve, or of the brain, the nature of the nervous or cerebral affection must be discriminated and ascertained before any remedy can be applied with the slightest chance of success; and even when this is accomplished, it is too often only to satisfy us that the disease is beyond the reach of art.

DEALS. A term originally applied to the thin slabs of timber cut out of log-stuff; but of late years it has been exclusively appropriated to such as are sent from timber-growing countries, in pieces from 8¼ to 9 inches in width by 3 inches in thickness. Deals are sold in London by what is called the St. Petersburg standard, whatever may be their length, the standard being considered to be 120 deals of 12 feet in length, or in fact 1440 feet lineal.

The best yellow and white deals for ordinary joiner's work are obtained from St. Petersburg, Christiania, Gefle, Dram, Dantzic; the best spruce-deals come from Christiania and Gefle; the best pine, red or yellow, deals come from St. John's in New Brunswick, and Portland in Maine; and the best pitch-pine is obtained from the ports of Georgia and South Carolina. The present duty upon deals is calculated upon the same rates as that upon battens; or 10*s.* per load of 50 cubic feet when imported from foreign countries, and 5*s.* per load with 5 per cent. additional when imported from British possessions.

The timber duties, some years ago, were so ill-regulated, in regard to the different rates charged on deals of different dimensions, as to interfere greatly with the natural course of trade. When the duty was charged at a fixed rate per great hundred (of 120) without reference to dimensions, and when that duty was on a moderate scale, it was the practice in the wood-producing countries to cut deals of those dimensions which would produce the greatest cubical quantity of sound wood from each tree; and it then rarely happened that deals were longer than 12 feet; but when the duty was greatly increased, and was charged according to their dimensions in classes with varying intervals, it became an object to introduce as much wood as possible at each specific rate of charge, and without due regard to economy in cutting. It is naturally to be expected that, with a rate of duty forming a large per-centage upon the first cost of the article, no person would import any deals much short of each of the maximum dimensions admissible at each rate of duty, but would sacrifice a part of the material when necessary, in order to escape a higher rate of charge; by this means the cost was necessarily enhanced to the consumer. The same motive did not operate with respect to the lower taxed deals of the English colonies, nearly the whole of which were accordingly brought of such dimensions that the duty amounted to one third more upon the cubical contents than it would amount to if the importers availed themselves of the provisions of the law in the way adopted by the importers of European deals. The duty charged upon the deals of Sweden, and still more upon those of Norway, was, by the working of the system, much higher than upon the shipments from Russia and Prussia; this arose partly from the different sizes to which the trees grow in the respective countries, and partly from the difficulty experienced in Sweden and Norway in conveying the trees, after they are cut, down rapid or narrow rivers to the place of manufacture. In France, where the duties on timber are low, deals are imported of all sizes suited to the convenience of the producers, and consequently the price is lower to the consumer; besides which, the quality of the wood is in some instances better, because thinner deals than are brought to England may be cut from the best part of the tree nearest to the sap. The deals of North America are inferior in strength and durability to those brought from the north of Europe, and to these last the preference is usually given for the flooring of houses and other purposes where durability is of importance. In building smaller houses, where cheapness is the principal consideration, Canadian deals are used. For small articles, such as mouldings, picture-frames, hat-boxes, musical instruments, as well as for many of the internal fittings of houses, and other purposes which call for the employment of wood that can be easily worked, Canada deals are preferred.

DEAN (French *Doyen*, and in Latin *Decanus*), a word which, at first sight, would appear to be allied to DEACON, but which has probably a different origin. Etymologists seem not to be agreed concerning the origin of the word; but the most usual origin assigned to it is the word *decem*, ten, as if a dean were a person who presided over collective bodies of men or things, in number *ten*. The word *Dean* is generally used as an ecclesiastical term. The French word Doyen is applied both to ecclesiastical and lay personages. Richelet ('Dict.,' art. *Doien*) says, that when applied to other than ecclesiastical bodies, it signifies the oldest of the body; thus the French used to speak of the Doien des Conseillers du Parlement. The Italian word *Decano* also signifies the head of a lay corporation, as well as an ecclesiastical dignitary. In Scotland it is used for the head of lay communities, but in England we believe it is generally confined to promotions or presidencies spiritual. It is, however, used in some colleges, as in University and King's Colleges, London, to signify the chief or head of a faculty chosen for a limited period. Deans in the colleges of Oxford and Cambridge are persons appointed to superintend the religious service in the college chapels, to enforce the attendance of the students there, and to exercise some control over them in other respects. In Scotland it is used as a lay title.

In England there are three classes of ecclesiastical presidencies to which the title Dean belongs:

1. *Deans rural.* The dioceses are divided into archdeaconries, and the archdeaconries into deaneries, below which there is no other subdivision till we come to parishes, the minutest of the proper ecclesiastical divisions of the country. The whole country is thus divided, with the exception of certain districts of no great extent, which claim to be exempt jurisdictions.

Those who contend for the derivation of the word dean, whence deanery, from decem, suppose that originally there were *ten* churches or parishes forming each of these deaneries. This is a very obscure point, and it is equally uncertain at what time this distribution of the dioceses was made. It appears, however, that there were deaneries before the Norman Conquest.

In each of these deaneries there was a clergyman who was dean; he was usually a beneficed clergyman within the deanery. His duties were to exercise a superintendency over the clergy, to preside at their assemblies, and to be the medium of their communication with their spiritual superiors. He had his public seal. He appears also to have discharged those duties which are now performed by clergymen called surrogates.

By degrees this office in the English church fell into disuse. The history or the reason of its decline is not very well known, for the advantage of having such an officer, especially where the archdeaconries were extensive, must have been always evident. The office, however, did by degrees disappear in one diocese after another, till it became totally lost. There was a dean of Chalke, in the diocese of Salisbury, as late as the reign of Charles II.; and a dean of Doncaster, in the diocese of York, in the reigns of George I. and II.

Attempts have been made to revive it. Berkeley, bishop of Cloyne, tried to establish the office again in Ireland; and soon after the late Dr. Burgess was made bishop of Salisbury, he did actually revive the office in that diocese, appointing Mr. Dansey, the rector of Donhead St. Andrew, rural dean of Chalke: this was in 1825. The Report of the Ecclesiastical Commissioners, 1835, under the head Territory, recommends that each parish shall be assigned to a deanery, and each deanery to an archdeaconry. There is a work, in two volumes quarto, entitled 'Horæ Decanicæ Rurales, being an attempt to illustrate by a series of notes and extracts, the name and title, the origin, appointment, and functions, personal and capitular, of Rural Deans,' by William Dansey, 1835.

The office existed in other parts of Christendom.

2. *Dean in a Cathedral Church.* The canons who formed the bishop's council were presided over by a dean; this has been the case from the remotest times. [CANON.] *Decanus et Capitulum* is the form in which all the acts of such communities run.

Anciently the deans were elected by the chapters; but here, as in other points, the royal power has encroached on the privileges of the Church. Now the form is for the crown to issue a *congé d'élire*, naming the person whom the chapter is to choose, in the bishoprics of ancient foundation; but in the bishoprics founded by Henry VIII., the king names the dean by his letters patent merely. In the former case the bishop is called in to confirm the election, and he issues his mandate for the installation of the person elected. In the bishoprics of St. David's and Llandaff the office of the bishop and dean is united in the same person.

3. *Deans in Peculiars.*—There are in England certain ecclesiastical promotions, in which the person holding them is called by the name of dean, and they seem to have all had anciently, as some of them have now, capitular bodies connected with them, and in all there is something peculiar in reference to their spiritual superiors, and in the jurisdiction exercised by them. The principal of them are—the dean of Westminster; the dean of the chapel of St. George, of Windsor; the dean of Christ Church, Oxford; the dean of the Arches; the dean of the King's Chapel; the dean of Battel; the dean of Bocking; the dean of Middleham, &c. If the history of these foundations were traced to their origin, it would be seen that they were ecclesiastical establishments, mostly of royal foundation, possessing peculiar privileges and a peculiar jurisdiction, which escaped dissolution when the framework of the ecclesiastical institutions of England underwent some alteration at the time of the Reformation. There are also *Honorary Deans*, as the dean of the Chapel Royal of St. James's Palace. The Bishop of London is dean of the province of Canterbury, and the Archbishop of Canterbury sends to him his mandate for summoning the bishops of his province in Convocation.

DEAN OF GUILD, in the municipal system of Scotland, is, as the title will naturally suggest, an officer of the merchant guilds, or societies of trading persons. An officer with this title used generally to be a member of the town council of every burgh, large or small; but by a clause in the Burgh Reform Act of Scotland (3 & 4 Wm. IV. c. 76, sec. 24), the functions of the dean of guild are appointed to be performed in each of the smaller burghs by some member of the council, chosen by the majority; and an officer chosen by the guildry, and entitled to sit as a member of the council, became peculiar to Edinburgh, Glasgow, Dundee, and Perth. By the Act 1593, c. 184, the dean of guild was invested with extensive judicial powers in commercial questions, but this jurisdiction has long been in desuetude. His principal powers are now of an ædile character. They are consuetudinary—not fixed by any general law, but dependent on the local customs of the various towns, so far as these have not been checked in their divergence from a general principle by the decisions of the courts. His authority is thus defined: "It belongs to the dean of guild to take care that buildings within burgh be agreeable to law, neither encroaching on private property, nor on the public streets or passages, and that houses in danger of falling be thrown down." The dean's authority is generally exercised in a court, of which he is the sole or the principal judge, according to local usage. His proceedings are sometimes conducted with the advice of a professional assessor.

The want of such an officer has been much felt in England; where somewhat analogous powers have latterly been conferred on Town Councils and Local Boards.

DEBENTURE (Latin, *debentur*, from *debeo*, to owe), formerly written debentur, is a kind of certificate used at the Custom House, which entitles a merchant exporting goods, upon which a drawback or bounty is allowed, to receive payment. The word has been used in some acts of parliament to denote a bond or bill, by which the government, railway, and other companies, are charged to pay a creditor or his assigns the money due on auditing his account. Debentures were used to secure the arrears of pay to the soldiery during the Commonwealth, and are mentioned in the Act of Oblivion, 12 Car. II., cap. 8. They are in use now in the receipt of Exchequer.]

DEBT, ACTION OF, lies for the recovery of a sum certain, or capable of being ascertained, due upon bond, deed under seal, or simple contract, or upon the judgment of a foreign or colonial court. It may also be maintained against a gaoler for the escape of a prisoner in execution, or upon a statute by the party grieved, or by common informer. Previous to 3 & 4 Will. IV. c. 42, the defendant in an action of debt on simple contract (except for rent) was allowed to wage his law, for which reason the action of *assumpsit* was frequently preferred; but the action of *debt* has ever since been the better remedy in such cases, the judgment being final in the first instance; and the distinction between the actions of *debt* and *assumpsit* has now been abolished for all practical purposes by the Common Law Procedure Act of 1852. The action of debt will not lie for money due by instalments till all the days are past, unless the payment be secured by a penalty, or the amount to be paid on each day be specified.

DEBT, NATIONAL. [NATIONAL DEBT.]

DECAGON, a figure of ten sides; but the term is most commonly applied to an equilateral and equiangular decagon, or a *regular* decagon. [REGULAR FIGURES.]

DECANTATION, an operation often resorted to both in common life and in chemical operations; it is the process of pouring off the clear portion of a fluid from that which contains suspended impurities, or from the impurities themselves when they have perfectly subsided. Sometimes this method is employed in order to avoid the use of filters; and there are cases in which it is preferable, as when the solution is so acid or alkaline that it would destroy paper or linen.

DECAPITATION, beheading; a punishment, in all probability, of very ancient date, and certainly known among the Greeks and Romans. Xenophon, at the close of the second book of the 'Cyropædia,' says, that losing the head was looked upon as the most honourable death. The decollation, as it is called, of St. John Baptist shows the existence of this punishment among the Jews under the Roman government of Judæa. Suetonius ('Calig.' c. 32) tells us that Caligula kept a soldier, an artist in beheading, who decapitated prisoners in his presence, fetched indiscriminately for that purpose from the gaols. Hoveden and Florence of Worcester agree that Earl Waltheof, who was beheaded by William the Conqueror in 1075, was the first Englishman who suffered that punishment.

In a manuscript quoted by Lysons, relating to the earls of Chester, it is stated that the serjeants or bailiffs of the earls had power to behead any malefactor or thief who was apprehended in the fact, or against whom guilt was proved by sufficient witness, or confession before four inhabitants of the four neighbouring towns; and it appears that the beheading of malefactors was the usual mode of execution in this county; for in a roll of 3 Edward II. it is called the custom of Cheshire. (Lysons' 'Magna Britannia,—Cheshire,' p. 299, from the Harl. manuscript 2009, fol. 34, b.)

From another part of this work it appears that criminals convicted of felony were punished in the same manner in the barony of Malpas; and that this power was even exercised by the several possessors of the moiety and fourth parts of that barony. In the 6 Edward II., David Bulkeley, serjeant of the peace to Richard Sutton, presented the heads of two felons executed for burglary; and Hugh Cholmondeley, serjeant of the peace to John de St. Pierre, presented the head of Thomas Burness, executed for theft, and had his fee called the radyng fee. (Ibid., pp. 677, 678, from the Harleian manuscript 2079, fol. 124 and 131.) The foresters of Hardwicke, in Yorkshire, had this punishment allotted to them for theft.

At a somewhat later period decapitation became a punishment more especially appropriated to the higher orders of society. Henry VIII. beheaded two of his queens. Elizabeth beheaded a sister sovereign. The High Court of Justice beheaded Charles I. In 1644, Archbishop Laud was condemned by the two houses of parliament to suffer death by hanging; and the only favour granted to him upon supplication, after delay and with reluctance, was, that his sentence should be changed to beheading. Losing the head still continues to be considered the most honourable mode of receiving capital punishment in England; but there has been no recent instance of its being inflicted. The last was in the case of the rebel lords of 1745.

In France, criminals capitally convicted are beheaded. [GUILLOTINE.]

DECAY. [EREMACAUSIS.]

DECEMBER. This month still retains the original name assigned to it in the Alban, and first Roman calendar adopted according to tradition by Romulus, in both of which it was the tenth, as the name signifies, or last of the year. Our Saxon ancestors called it Mıð-ƿınteꞃ-monað, *mid-winter-month*, and ᵹehul or *yule-month*, from ᵹehƿeol, *a wheel*, emblematical of the sun's revolution or return in his annual course.

December was anciently consecrated to Saturn, and in it the saturnalia were held; Alexander ab Alexandro, in his 'Genialium Dierum Libri sex,' says to Vesta, the daughter of Saturn. In the Alban calendar this month consisted of thirty-five days. Romulus reduced it to thirty; and Numa to twenty-nine days. Julius Cæsar restored the day of which Numa had deprived it; and Augustus added another day, which it still retains. Commodus, who attempted to change the names of several of the months, with the assistance of his flatterers, gave that of Amazonius to this, in honour of his mistress, Martia, whom he delighted to see clothed in the Amazonian habit.

DECE'MVIRI, or ten men, the title of various magistrates or functionaries in ancient Rome.

1. *Decemviri legibus scribendis*, that is, ten men for the purpose of making a new code of laws, were certain extraordinary magistrates, or rather a commission of ten men, invested with the power both of framing a new code and administering the republic. In the early times of ancient Rome the judicial power belonged to the kings, and, after their expulsion, to the consuls, who did not decide according to written laws, but only according to usages and customs. As such usages and customs were necessarily subject to doubt, and as the consuls were chosen only from the patrician order, the disputes between patricians and plebeians were probably often decided partially in favour of the former; and this would happen more especially in criminal cases, for which no certain law was provided. These circumstances led to the institution of the decemvirs.

After many violent struggles, the senate and the plebeians, B.C. 453, agreed that certain written laws should be framed, to which every citizen, without any distinction, should be subject. A commission of three members was appointed to visit Athens for the purpose of getting a copy of Solon's laws, and making themselves acquainted with the institutions of other Greek states. (Liv. iii. 31.) The commissioners having returned at the expiration of two years, the tribunes immediately called for the new code. For this purpose another commission, consisting of ten members, was named by the comitia centuriata. Uncontrolled power, both administrative and judicial, without any appeal, and accompanied with the suspension of all other magisterial offices, including the consuls and tribunes, was conferred on them. The names of the ten commissioners are recorded in Livy (iii. 33) and Dionysius Halicarnassus ('Antiq. of Rom.' xi. 56). Appius Claudius was the leading member of the ten: he was the soul of the commission, and directed all the business. The decemvirs conducted themselves with great moderation and justice. On the expiration of their year of office, they had framed a body of laws, distributed into ten sections, which were approved by the senate and the comitia, and engraved on ten tables of metal.

As the new laws seemed imperfect in some respects, a new commission was named, at the head of which was the same Appius Claudius (Liv. iii. 35). But the decemvirs now began to behave in a very different manner; they became real tyrants, and formed a most pernicious oligarchy. They framed, however, several new laws, which were approved by the centuries and engraved on two tables. Though their commission and the year of their office were now at an end, they still would not resign, but continued to hold their power in the year 447 B.C. and to exercise it in a most arbitrary manner. Appius Claudius, by a most unwarrantable decision, declared Virginia, the daughter of Virginius, an officer in the Roman army, a slave, because she had refused to listen to his dishonourable proposals. Virginius, the father, to save his daughter from violation, murdered her in the public place, and, with the bloody knife in his hand, called on the people to take vengeance on their oppressors. Both the citizens resident in Rome and the army united themselves to overthrow the tyrannical power of the decemvirs, who were forced to abdicate, and the ordinary magistrates were re-established. Appius Claudius was put in prison, where he died.

The ten tables of the former and the two of the latter decemvirs together form the laws of the twelve tables.

2. *Decemviri litibus judicandis*, that is, ten men for the purpose of deciding suits, formed a court of justice under the superintendence of the prætor, which was established about B.C. 237. The establishment of this body was caused by the great increase of suits, which rendered it impossible for the prætor to get through the business of his court. As to the powers of these decemvirs, we have no distinct notices.

3. *Decemviri sacris faciundis*, were an ecclesiastical college, the members of which were elected for life. The care of the Sibylline books belonged to them, and they were consulted by them on important occasions.

4. *Decemviri agris dividundis*, were a commission for the temporary purpose of dividing lands among the colonists when a new colony was to be established.

DECIMAL FRACTIONS. [ARITHMETIC; FRACTIONS.]

DECIMAL NOTATION. [ARITHMETIC; NUMERATION.]

DECIMAL SYSTEM OF WEIGHTS AND MEASURES. [WEIGHTS AND MEASURES.]

DECLARATION (declaratio), in law, is the statement of his case by the plaintiff in an action at law: in a real action it is properly called a count (narratio). It corresponds to the *bill* in chancery, the *libel* in ecclesiastical courts, and the *petition* in the court of divorce. [PLEADING.]

DECLARATOR, ACTION OF, a form of procedure peculiar to the Court of Session in Scotland. Its name explains its nature, which is an action to have it judicially declared that a certain right exists, with reference to property, or that a certain character, as, for instance, husband or wife, or heir or trustee, exists in a particular person or persons. It is not necessary that the party who brings the action should demand any immediate service from the law, or that there should be any adverse party. It may be raised by persons in doubt how they ought to act to avoid the consequence of a breach of the law, and thus it is frequently had recourse to by public officers. A person whose legitimacy is questioned, though no one may be at the moment denying his right to possess any property of which illegitimacy would deprive him, may bring an action of declarator of marriage and legitimacy to have his claim judicially established. The principle of the declaratory conclusion is often admitted into other actions where there are many complex claims. The court lays down certain rules, applicable to the circumstances, by which the claims of individual parties shall in the ultimate decision be tried. The action of declarator has been applied to many useful purposes, but it is likewise like some similar forms of procedure in chancery in England, capable of abuse.

It has been proposed to vest a jurisdiction similar to that thus exercised by the Scottish courts, in the Court of Chancery; but the proposal has not yet assumed sufficient shape to permit of its forming the subject of legislation. The Court for Divorce and Matrimonial Causes has, however, by a recent statute, been empowered to declare the *status* of persons being or claiming to be natural born subjects of the Crown; by establishing their legitimacy or the validity of the marriage of their parents. (21 & 22 Vict. c. 93.)

DECLINATION. When a star is not in the equator, the angle made by two lines drawn from the spectator's eye, one to the star, the other to the nearest pole, is called its polar distance. The complement of the polar distance, or the angle subtended by the star and the nearest point of the equator, is the declination of the star. It is called north or south according as the star is north or south of the equator. The declination (it is becoming very common to use the polar distance in preference) and the right ascension [ASCENSION, RIGHT] are the usual co-ordinates to which a star's place is referred. Confining ourselves here to declination, we must merely remark that the effect of a diminution in declination is to bring the star nearer to the equator, and its time of appearance above the horizon nearer to twelve hours. The length of a star's (or of the sun's) time above the horizon is found as follows: Multiply together the tangents of the latitude of the place and of the declination of the star. If the answer be greater than unity, the star is too near the north pole to set, or too near the south pole to rise (according as the declination is north or south); if equal to unity, the star grazes the horizon at the north (or south) points, but does not set (or rise); if less than unity, find the angle which has the preceding product for its cosine, convert it into time at the rate of 15° to an hour, and the defect from twelve hours is the half of the duration required, expressed in sidereal time.

DECLINATION OF THE MAGNETIC NEEDLE (or Variation of the Magnetic Needle), is the angle which the horizontal needle makes with the geographical meridian of any given place.

It has been usual among European writers to refer the discovery of the declination or variation of the needle to Columbus, on his first voyage of discovery in 1492. This opinion rests entirely on the testimony of the son of that great navigator, who states the circumstance in the life of his father, with considerable probability of its being a real case. It is however hardly to be conceived, that the compass should have been in use amongst the enterprising sailors of Europe, upon voyages so extensive as were then frequently undertaken, without the circumstance being not only observed by some, but known to all who were engaged in maritime affairs. At all events, it appears from various printed works and manuscripts to have been familiarly known very soon afterwards to all the commercial nations of Europe.

When it was found that the needle declined from the meridian by different quantities in different places, it was still assumed that at each given place the declination was constantly the same. In 1581 Burrough published his 'Discourse on the Variation of the Compass,' in which he states as the result of numerous observations, that the declination at Limehouse was 11° 15′ E; but in 1633, Gillebrand, the Gresham professor of geometry, found by careful observations that it only amounted to 4° 5′ E. It has indeed been stated by Bond, that the variation of the declination was first discovered by Mair, and secondly by Gunter; but as he gives us no authority for this assertion, we are unable to judge of its truth or falsehood. Bond was addicted to paradox, and his statements should therefore be received with caution.

Careful observations (subject however, to several sources of then unsuspected error) have been made from that period down to the present time, and they all concur in showing that this variation of the declination is continually going on, though not with a uniform angular motion. It was therefore inferred, that the needle would continue to revolve round the horizon by slow degrees, till at last it came round again to any given position; and it appears to have been suspected by some, that the irregularity of its indicated motions was only apparent, and arising either from the imperfection of the instruments employed, or the inaccuracy of the observations themselves. The scientific world was, consequently, not prepared to expect the results of Major Sabine's observations on the declination, and the truth which they unfolded, when in 1818 he determined it to be 24° 30′ W., and four years afterwards to have retrograded to 24° 12′, at London. Subsequent observations, however, bear out this conclusion; and not only do the observations made in this country, but throughout Europe, undeniably establish the fact, that the western declination had about 1818 or 1820 attained its maximum value, and that the needle, instead of continuing to gradually move round the points of the horizon, is now returning towards the geographical meridian. The general opinion is therefore, that the needle performs a series of oscillations on each side of the meridian, and after attaining its extreme limit returns again through another slow oscillation. As no easterly declination equal in quantity to the recent westerly maximum value has been observed with care, we are left only to conjecture on this point. If, indeed, we adopt this hypothesis, and take Bond's authority for the declination being 0 in 1657, we ought to expect on such an hypothesis that it will be 0 again in 1979, and attain its greatest easterly value in 2140. We are not, we confess, very devoted believers in the opinion that its oscillations are regular; and we think we could furnish strong reasons for our scepticism on this head: but while so few steps have been made towards a satisfactory theory of terrestrial magnetism, it would be rash to affirm that conclusive reasons can be given for either one opinion or the other. At all events, the popular hypothesis depends entirely on an analogy supposed to hold true between the pendulum and the magnetic needle, in a case where the analogy is unphilosophically applied, that is, where the analogy of the causes is by no means apparent, and where there even seems to be a direct contrast between them.

The daily variation of the declination was first observed by Graham in the early part of the last century. He found by very careful experiments upon excellent needles, that the declination was not uniform during the whole period of a day; sometimes being to the east, and sometimes to the west of the general mean declination at the time and place of observation. Canton, less than half a century later, made a considerable number of observations, and a great number of experiments on a subject, which he, like Graham, supposed to be collateral with it,—the influence of temperature upon the intensity and direction of the needle. These inquiries were pursued with great success by Mr. Christie, of the Royal Military Academy, and M. Kupfer, of Casan. Separate parts, too, of this inquiry were attended with very curious results in the hands of Mr. Barlow, likewise of Woolwich Academy, on the influence of high temperatures; and by Colonel Beaufoy, in his careful observations on the actual daily variation for several years before his death.

This article is but a slight sketch of the general state of the science. We refer to the articles MAGNETISM, TEMPERATURE, and VARIATION, for details of the methods of observation and the theoretical views which have been proposed.

DECOCTIONS are formed by subjecting the harder parts of plants which are not easily penetrated by liquids, or are insoluble in water of a low temperature, to the process of boiling, generally in water, but sometimes in oil. By this means much of the substance is dissolved, and the active principles of the plant are imbibed by the fluid, which is then used medicinally either internally or externally. Porcelain vessels, or those glazed with salt (Bristol ware), are to be preferred to metallic vessels in most cases. This method of extracting the medicinal properties of plants is inadmissible when their powers depend upon any aromatic or volatile principle, such as essential oils, which are dissipated by a high temperature. In many other instances this process is not only unnecessary but injurious, being employed when infusion is sufficient, even when cold water is used for the purpose of infusion. Of this nature are all purely mucilaginous substances, such as marsh-mallow (*Althea officinalis*), quince-seeds (*Cydonia vulgaris*), &c., from which Trommsdorf has shown that a purer mucilage, which keeps longer, may be obtained by cold water. All substances, the astringent properties of which depend upon the presence of tannic acid, such as oak-bark, tormentil-root, &c., have their astringent power impaired or completely destroyed by long boiling. Besides, boiling dissolves many principles, such as starch, &c., which are quite inert, and which do not contribute to the efficacy of the medicine, while their presence disposes the decoction to decomposition, a process very apt to occur in decoctions, and rendering them unfit for use in a few days or hours. Decoction is a mode of preparing substances most suitable to those which are both nutritious and medicinal, such as Iceland moss (*Cetraria islandica*). But when the bitter principle alone is wished, cold infusion is better. Many principles which are dissolved by the water at a boiling temperature are deposited by it by cooling, on which account the liquid should always be strained while hot, and the contents of the bottle shaken up before each dose be poured out. Aromatic liquids are frequently added to the fluid after it is strained; or the aromatic substance may be placed at the bottom of the vessel into which the hot decoction is strained, and, after being allowed to infuse for a few hours, may then be applied to the use intended. A better method, however, is to add some aromatic tincture after the straining, as the presence of the spirit retards the tendency to decomposition, while it imparts the flavour and qualities of the substances from which it had been prepared.

To render the heat steady, or uniform, various expedients are resorted to, such as, more especially on the Continent, a *bain marie*, or sometimes Reindorf's apparatus; a steam or vapour bath is also used. In this country, where spirit of wine is expensive, gas has lately been used with excellent effect.

To bring the temperature of the water up to the proper degree as rapidly as possible, and thereby shorten the process, as well as lessen the risk of empyreumatising the ingredients, the introduction of a jet of steam is attended with advantage, especially in forming decoction of sarsaparilla.

To obviate some of the objections to decoctions, what are termed *Decocta infusa* have been introduced. The more insoluble substances are first put into the water, as in common decoctions, then after boiling half an hour or an hour, according to their nature, the more soluble matters, or the boiling water, charged with what it has dissolved, is poured on the other ingredients, and having stood the usual time, as for a common infusion, is strained. A better plan would be the entire disuse of decoctions.

DECOMPOSITION. When a compound body undergoes an entire change of properties, either spontaneously or from chemical agency, it is said to be decomposed; thus, during fermentation, whether the spirituous, acetous, or putrefactive, the substance undergoing it suffers decomposition, and its elements recombine so as to form new compounds. This distinguishes it from mere mechanical division, to whatever extent that may be carried. [ANALYSIS; FERMENTATION.]

DECREE, DECRETA'LES. The term decree (decretum) denotes a decision or order by a competent power or magistrate, by which some doubtful or disputed point of judicial inquiry is determined. In England, the final judgment of the Court of Chancery is usually called the decree. In Scotland, every judgment must contain a decree or decerniture, which is effected by using the word "Decerns."

It was usual among the Romans, in doubtful cases, to take the opinion of lawyers, which were called "responsa prudentum," obtaining the authority of law when they were unanimous. (Gai. 1-7.) When all legislative power was centered in the emperor, it became the custom to ask for his opinion in disputed cases. The decision was called a rescript, and at once became a part of the imperial decrees or constitutions.

In ecclesiastical matters the clergy, following out the precedent of the Roman empire, early introduced a practice of asking the opinions of the bishops, particularly of the bishop of Rome. The replies of the pope ultimately obtained great authority, though they had not the force of laws, so long as the legislative power belonged to the councils. In the 12th century, the pope being regarded as the highest ecclesiastical authority, the whole ecclesiastical legislation was centered in him, and the papal decrees became the only source of ecclesiastical law, as the imperial constitutions had been for the civil law. The decrees of the pope, which are called *decretales*, may be defined as decisions of the popes in ecclesiastical matters of law. The decrees of the popes retained their authority as law till the 14th century, when the power of the holy see began to decline. [CANON LAW.]

DECREE. [EQUITY.]

DECREMENT. [INCREMENT.]

DECREPITATION. A term applied in chemistry to the slight explosions produced when certain crystallised salts are suddenly exposed to a high temperature. The little explosions producing the crackling noise of decrepitation, are caused by small portions of water imprisoned within the crystals being converted into steam, which acquires sufficient tension to tear asunder the walls of the chamber within which it is confined. Common salt thrown upon a bright cinder fire affords a good illustration of decrepitation.

DECURIO'NES, a term which denotes certain persons who correspond to the senate at Rome, in the Roman towns and colonies in Italy which enjoyed free municipal rights. The body of the decuriones was called ordo decurionum, and in later times also curia decurionum, whence the members of the order were also designated by the name curiales. The whole administration of the internal affairs of such towns and colonies was in their hands. They were required to have a certain estate, and to be at least twenty-five years old. It is commonly said that their number was ten, but it was usually greater, and sometimes amounted to 100 members. At the head of the body were the duumviri, that is, two men, like the two consuls, who presided in the Roman senate. Those municipal corporations forming, as to their internal administration, little republics, the citizens had the right of choosing the duumviri just as the citizens of Rome elected their consuls; but under the emperors they were deprived of this privilege, and the decuriones at the same time lost their power. The municipal corporations were administered by officers appointed by the emperor; and the decuriones were only employed to receive the taxes, which subjected them to a great responsibility. The office of a decurion being now considered as a burden, was no longer sought after, and lost its former importance. (Sigonius, 'De Antiq. Jur. Ital.' ii. 4.)

DEDICATION. [CONSECRATION.]

DEED (in law), an instrument in writing or print, upon paper or parchment, comprehending the terms of agreement between parties able to contract, duly sealed and delivered. Deeds are of two kinds, indented and poll: a deed indented is called an indenture, and originally had, and indeed now sometimes has, a waving line cut (*in modum dentium*) on one of the edges of the material upon which it is written, usually the top edge, and when the deed consists of more sheets than one, on the first sheet only. The term indenture implies that the deed is of two parts, and that they were divided by the line in order to afford additional means of authentication; but, except in the case of leases, marriage settlements, partnership deeds, and some few others, there are seldom more parts than one. In deeds effectuating modern transactions, indeed, the expense of stamps is so heavy, that frequently, where two or more parties are equally interested in a deed, it is deposited with some person for their joint use. Hence the term indenture, in common acceptation, now implies little more than that the deed is made by and between two or more parties. Anciently some word, as, for instance, "chirographum" (whence "chirograph"), was written in capital letters upon the part where the parchment or paper was to be divided, and afterwards cut in an indented, or in some cases a straight line.

The stat. 8 & 9 Vict. c. 106, enacts that a deed executed after Oct. 1st, 1845, purporting to be an indenture, shall have the effect of one, though not actually *indented*.

A deed poll is cut even, or polled at the edges, and is usually of one part only; that is, the deed of one party, or of several parties of the same part. The form commences in the mode of a declaration: "Know all men by these presents, that," &c. The form appropriated to an indenture or a deed among several parties is, "This indenture, made, &c., between, &c. Witnesseth," &c.

A deed, to be absolute and irrevocable, must be founded on a valuable or good consideration, untainted by anything immoral, illegal, or fraudulent, though a gift or voluntary conveyance will be effectual as between the parties, and is only liable to be questioned in certain cases by creditors or subsequent purchasers; and a voluntary deed may become irrevocable by a subsequent sale by the grantee of the subject-matter conveyed by it.

Ancient deeds were short, and suited to the simplicity of the times. When transactions became more complicated, it was customary to divide deeds into several formal parts; but it is not absolutely necessary that a deed should be so divided, provided there are sufficient words to show the meaning and intention of the parties. These formal parts are: 1. The premises; that is, the date, the parties' names and description, the recitals, the consideration and receipt thereof, the grant, the description of the things granted, and the exception, if any. 2. The habendum, which defines the estate or interest to be granted. 3. The tenendum, which was formerly used to express the tenure by which the estate granted was to be held; but since freehold tenures have been converted into common socage, the tenendum has grown out of use. 4. The reddendum, the reservation of some new thing, as rent, to the grantor. 5. The condition (if any) annexed to the grant. 6. The warranty. 7. The covenants. The office of these two last, in modern conveyances, is served by special covenants for the validity of the title, and to do or abstain from doing certain specified acts. 8. The conclusion, which mentions the execution, &c.

Previous to its execution, the deed should be read, if any of the parties require it; or, as to that party, it may be avoided. The modern mode of executing deeds is by signing, sealing, and delivering. Signing is not essential to the validity of a deed, though it is required as to less formal instruments by the statute of frauds, 29 Ch. II. c. 3; but sealing is absolutely necessary, which is the most ancient mode of authentication, and has been in use from the earliest times. At present the seal affords no real security against fraud, for any impression upon wax or other substance employed is sufficient; indeed, it is generally affixed by the stationer who engrosses the deed, and it is not even necessary that there should be a seal for each party: one is sufficient for all. In some of the American states the impression upon wax has been disused, and a flourish with the pen at the end of the name, or a circle of ink, or a scroll, is allowed to be a valid substitute for a seal. The last essential to the due execution of a deed is delivery, except in the case of a corporation, where sealing by the common seal has the effect of delivery. The usual manner of delivering a deed is for the executing party to say, "I deliver this as my act and deed;" but any less formal mode by which the party signifies his intention to deliver it will be effectual. A deed may also be delivered as an escrow,—that is, to a third person to keep till something is done by the grantee: when the condition is performed the deed becomes effectual. A deed takes effect from the delivery, and not from the date; and, therefore, if it have no date, or a date impossible, the delivery ascertains the time from which it is to take effect. Evidence is admissible also of delivery on a day different from the date written. The execution is usually attested. Enrolment and registration are rendered necessary in some cases by statutory enactment, and the revenue laws have imposed certain stamps upon every description of deeds, the absence of which prevents them from being admissible in evidence.

The principal rules for the interpretation of deeds are, that the effect be fair and reasonable, and as near as possible to the apparent intent of the parties as the rules of law will admit; that the construction be made upon the entire deed, and not upon disjointed parts; that where the intention is clear, too minute a stress be not laid on the strict and precise signification of the words; and that if there be two clauses totally repugnant to each other, the first shall be received, and the latter rejected. There are many other rules of construction, which are exactly the same in courts of law and equity. Courts of equity also rectify mistakes in deeds, and give relief in cases of fraud, and where instruments are lost, &c. [EQUITY.]

After execution, a deed may became void by erasure, interlineation, or other alteration in any material part; but, generally speaking, such alterations will be presumed to have been made before the execution, if nothing appear to the contrary, or there be no cause to suspect that it has been done in a clandestine manner. A grantee may also disclaim the grant or disagree thereto; and a deed may be destroyed or cancelled, but such destruction or cancellation will not revest the thing granted in the grantor, though all personal engagements established by the deed between the parties will be put an end to.

A confirmation is an assent to an estate or interest already created, by which act the person assenting confirms and gives validity to the estate or interest so far as he can. A confirmation can only have this effect with respect to estates voidable or defeasible; it has no operation upon estates which are absolutely void. (Butl. n. Co. Litt., 295 *b*.)

(Shep., *Touchstone*; Dixon; Co. Litt.; Cruise's *Digest*.)

DEFAMATION; the speaking slanderous words of another. The injured party may bring an action to recover damages, but to enable him to succeed, it is absolutely necessary that the words should contain an express imputation of some crime or misdemeanor which would make him liable to punishment; or, if the words are not actionable in themselves, some special damage should be proved to have resulted from them to the plaintiff. There are certain cases, however, where words are spoken of a tradesman or professional person in the way of his trade or profession, as that a tradesman is insolvent, or that an attorney deserves to be struck off the roll, in which the plaintiff, by reason of the character he fills, may recover damages. Of the first class the following case affords an illustration. A churchwarden was accused by the defendant of having stolen one of the church bell-ropes: it was held that, as the property of the bell-ropes was vested in the churchwarden, the words did not impute a crime to the plaintiff for which he was punishable, and consequently that the action could not be maintained. In former times, actions for slander were very rare; and though it has been frequently said that actions for words spoken in heat or anger, suddenly and without deliberation, ought not to be encouraged, yet it has been truly observed (by Wray, Ch. Just.) that unless the party injured by false and malicious scandal had a remedy at law, it would lead to personal violence, and the consequences might be fatal. In most cases, malice in law may be inferred, but in actions for slander *primâ facie* excusable on account of the cause of publishing the slanderous matter, malice in fact must be proved; it is scarcely necessary to observe, that where special damage is proved, the existence of malice is immaterial. Defamation is also punishable in certain cases by indictment and criminal information. Where the slanderous matter is spoken of a peer, the offence is termed scandalum magnatum, and is made punishable by various statutes: this mode of proceeding however may be said to have become obsolete.

The ecclesiastical courts formerly had power to punish for defamation: but these courts could only inflict punishment by way of penance; they could not award damages; and this useless but mischievous jurisdiction has consequently been abolished. An action may also be maintained for slander of title to an estate or property; but in this case the plaintiff must prove malice express or implied: it is not sufficient that the defendant should allege title in himself, or make objections to the title of the plaintiff if he had reasonable grounds for so doing. (Cowel; M'Culloch; Selwyn, *N.P.*). [LIBEL; SLANDER.]

DEFEAZANCE (from the French verb *défaire*, to make void) is an instrument which defeats the force or operation of some other deed, estate, or interest, upon the performance of certain prescribed conditions. In this manner mortgages were formerly made, the mortgagor enfeoffing the mortgagee, and at the same time executing a deed of defeazance. Defeazances being discountenanced by the courts, as affording opportunities for fraud, have long ceased to be used as applicable to titles, it being far better to make the conditions apparent on the deed itself.

Defeazances to bonds, recognizances, &c., merely state the conditions on which the instrument is to be void. The defeazances to warrants of attorney and cognovits must be written upon the same paper or parchment as the instruments themselves.

DEFENCE OF FORTRESSES. [SIEGE.]

DEFERENT, a circle or oval curve on which the centre of another oval moves, while a planet is supposed to move round the latter. The term is one of the PTOLEMAIC HYPOTHESIS. Thus the earth's orbit, to choose an example out of the modern system, is a deferent on which the moon's orbit is carried.

DEFILADING is that part of the art of fortification the object of which is to determine (when the intended work would be commanded by eminences within the range of fire-arms) the directions or heights of the lines of rampart or parapet, so that the interior of the work may not be incommoded by a fire directed to it from such eminences.

If it be required, with a given height of parapet, to approach obliquely as near as possible to an eminence, the following process is adopted; the situation of the rampart or parapet at that extremity of the intended line which is farthest from the eminence being also given. A line is supposed to be drawn from the commanding eminence, or rather from a point about eight feet above it, through another point which represents the crest or summit of the intended parapet at the given place, and to be continued till it intersects the natural ground in rear of that part of the line of parapet. This crest is considered as the vertex of a cone whose base is a circle, on the ground, having for its radius a line equal to the distance from the parapet to the rear extremity of the ground to be protected (which distance, however, must always be less than that of the intersection above mentioned). Then a line being drawn on the plan, from the point vertically under the given crest, parallel to a line drawn from the said intersection and touching the circle, will be the direction of the intended rampart or parapet, whose height must be everywhere equal to that which was given. By this construction all the lines of fire from the commanding eminence, and passing closely over the crest of the parapet, will be in a plane meeting the ground on that eminence, and touching the convex surface of the cone.

Again, if it be required, when the plan of the work is determined, to ascertain the heights of a rampart or parapet in different places, so that the interior may be protected from the fire of the enemy on a commanding eminence beyond, the relative heights of the principal inequalities of the ground with respect to some horizontal plane, technically called the plane of comparison (which generally passes through the highest or the lowest point), must be found by the spirit level. An oblique plan, technically called the plane of site, must be imagined to touch the summit of the eminence in front, to pass above all the intermediate ground, and to meet that in rear of the work; then the relative heights, with respect to the plane of comparison, of the several points in the plane of site which are vertically above the inequalities before mentioned of the natural ground, must be computed, and the differences (which express the heights of the plane of site above the natural ground in such places) being added to the given height which the rampart or parapet is to have above the plane of site, the sums will express the heights to which the works are to be raised above the natural ground at the same places.

When the work is of small importance, the elevations of the parapets above the ground are generally determined by the eye, thus: Pickets are planted in convenient places, chiefly at the angles of the intended work (the plan of which has been already traced on the ground), and on the summit of the commanding eminence, the picket in this place being about eight feet high. The visual rays being supposed to proceed from the top of this picket to two or more points, which must be also eight feet above the ground, in rear of the work, the intersections of these rays with the pickets planted on the magistal or ground line of the work, will show the heights to which the parapet is to be raised at those places in order that the interior may be effectually protected.

A similar process is employed when it is required to protect the defenders of any parapet from the fire of the enemy on a commanding eminence in their rear; in which case it is frequently necessary to raise, in the interior of the work, a mass of earth, which is called a traverse or a parados, according to its situation.

DEFILE, in military writings, is a name given to any narrow way. Every piece of ground which, in consequence of local impediments, can be passed by a column only on a narrow front, is called a defile. Such are roads along valleys, between walls or hedges, or over dykes raised across marshes. Sometimes also the term is applied to a street in a village, and to the path over a small bridge.

DEFINITE PROPORTIONS. [ATOMIC THEORY.]

DEFINITION (*definire*, to mark out a boundary) is the process of stating the exact meaning of a word, by means of other words. From so boundless a subject, we can only select a very few points, such as have reference to the most common uses of the term. In the first place, it is evident that all definition contains a species of fallacy, if considered as an absolute determination of the meaning of words. *Quis custodiet ipsos custodes?* who shall determine the meaning of the words which make up the definition? The process of definition can never appear satisfactory unless it be considered as a transition from many words to the single term which it is agreed shall stand for their meaning, be that what it may. All attempts at absolute definition must end in confusion of ideas.

But at least, perhaps it may be said, the mathematical sciences are founded upon exactness of definition. Nothing is more common than this assertion coupled with another, namely, that these sciences depend entirely upon definitions. In a certain sense both are true, but that sense is not the most frequent meaning of them. The exactness of mathematical definition is not of arbitrary construction, but a consequence of the exactness of the notions which all men have, or may be made to have, upon the things which the words represent. There is no exactness in the fundamental definitions of mathematics, verbally considered, but only much confusion arising from the attempt to introduce conventional accuracy. The words "straight line" carry with them their own meaning, and even explain the attempt which is made to explain them; for no one would easily guess what sort of line it is which "lies evenly between its extreme points," unless he were aware that it is a "straight" line which these words attempt to describe.

Definition may either be purely nominal, or it may be such a description of the thing defined as amounts to a statement of some one of its fundamental properties. The first we see in the words "isosceles triangle," the definition of which is a simple announcement that we intend to use a Greek term. The second may be seen in the article CONCAVE AND CONVEX, in which the definition is made by means of an absolute mathematical property of the thing defined: the relative position of the spectator, the curve in question, and a straight line, do not enter into the notion which the words immediately suggest. The method of Euclid is to supply a rough and descriptive definition addressed to the common notion of the word, followed by an assumption of a mathematical property under the shape of an axiom. Thus a straight line is "that which lies evenly between its extreme points;" while the real definition, or distinction between straightness and every thing else is contained in the axiom "two straight lines cannot enclose a space." Every attempt at mathematical definition, which does not rest upon the selection of a substantive property of the thing defined, to be the test of its existence, is either the mere substitution of words for words, or an attempt to make that mere substitution effect something more than lies in it to perform.

The conditions of a good definition are: 1, perfect axiomatic evidence that the property which is made the distinguishing test belongs to the object intended to be defined, and to nothing else; 2, entire separation of the part of the property, if any, which admits of being demonstrably connected with the notion defined, from that which contains the assumption; 3, the introduction of the definition in the proper place, namely, when the necessity for a new verbal representation has begun to appear.

The mere verbal definition is not to be regarded as taking for granted the existence of the thing defined. When Euclid defines *parallel lines*, he does not require consent to the proposition that parallels exist. All he is to be taken as asking is this: If there be two straight lines which being in one plane never meet, let them be called —*parallels*.

DEFLAGRATION is a term employed to denote the sparkling combustion of substances without violent explosion: thus when nitre and sulphuret of antimony are mixed and ignited or thrown into a hot crucible, the combustion which occurs is of the kind termed deflagration.

DEFLECTION. A term applied to the distance by which a curve departs from another curve, or from a straight line; and also to any effect either of curvature or of discontinuous change of direction. It is used where any "bending off" takes place, which is in fact the etymological meaning of the word.

DEGREE. [ARTS; UNIVERSITIES.]

DEGREE OF ANGULAR MEASURE. [ANGLE.]

DEGREE OF AN EQUATION. The degree of an algebraical term is the number of letters which enter into it as factors. Thus x^2y^3 is absolutely of the fifth degree; but of the second degree with respect to x, and of the third with respect to y. The degree of an equation is the degree of its highest term.

DEGREE OF LATITUDE, OF LONGITUDE, OF MERIDIAN, &c. [GEODESY.]

DEIFICATION. [APOTHEOSIS; CONSECRATION.]

DEISM properly means belief in the existence of a God, but is generally applied to all such belief as goes no farther, that is to say, to disbelief of revelation. It is always applied dyslogistically, and frequently merely as a term of reproach. But the identical word, in its Greek form, *theist*, is not a word of disapprobation, and, consistently with established usage, may be appropriately applied as opposed to atheist, when the latter term is correctly used. For it must be observed that the term atheist has been not unfrequently employed in the sense of an unbeliever in Christianity, though at the same time professing theism.

DEL CREDERE COMMISSION. [AGENT.]

DELEGATES, THE COURT OF, was formerly the great court of appeal in ecclesiastical causes, and from the decisions of the Admiralty Court. It was so called because the judges had delegated to them by commission under the great seal the appellate jurisdiction of the crown in these matters. These delegates usually consisted of judges of the courts at Westminster and doctors of the civil law, but lords spiritual and temporal might be joined. This court was first created, in consequence of the statute 25 Henry VIII., c. 19, which transferred to the crown the authority of the pope to entertain appeals from the courts Christian.

By the constitutions made at Clarendon, 11 Henry II., the practice of appealing to the pope had been condemned; but though frequently checked, it was never thoroughly broken off until the final rupture with the court of Rome, in the reign of Henry VIII. After sentence by the delegates, the crown might grant a commission of review; but the power was rarely exercised, except upon the ground of error in fact or in law, and it was usual to refer the memorial praying for a commission of review to the chancellor, before whom the expediency of granting the prayer was argued.

By 2 & 3 Wm. IV. c. 92, the Court of Delegates was abolished, and its powers and functions were transferred to the crown in council [PRIVY COUNCIL]. The same statute enacted, that no commission of review should in future be granted. This jurisdiction is now exercised by the Judicial Committee (3 & 4 Wm. IV. c. 41).

DELIAN PROBLEM. [DUPLICATION.]

DELIQUESCENCE, the change of form which certain bodies undergo from solid to fluid by exposure to the air, and absorbing moisture from it.

There are many substances which partake of this property: among the more remarkable are potash, carbonate of potash, chloride of calcium, and nitrate of copper; all these will in a short time attract sufficient water from the air to become fluid in it. Other saline bodies are deliquescent only in moist air, such as chloride of ammonium and nitrate of ammonia.

Certain deliquescent salts, and more especially chloride of calcium, are employed for the purpose of drying gaseous bodies which are the subject of experiment.

DELIRIUM TREMENS, a disease of the nervous system, to which persons addicted to alcoholic drinks, though not exclusively, are peculiarly liable. As its name indicates, its principal symptoms are delirium and trembling. The delirium is a constant symptom; but the tremor is not always apparent, or does not exist. The delirium is always attended with sleeplessness: the patient is busy, and constantly talking, but is seldom or ever angry or violent. If he is questioned, he answers rationally, but speaks in an agitated and suspicious manner; he mostly does whatever he is told, and is frequently anxious to oblige. His thoughts, however, wander very quickly from objects around him, and he is apparently surrounded by the scenes of his imagination. Here, according to his occupation, he is busily engaged. If he is a master, he will order; if a servant, he will be anxiously obeying his master's commands. The sailor, the soldier, the coachman, all get busily engaged in their occupations. His thoughts are mostly distressful and anxious; he fancies he is in debt, that persons are persecuting him, that reptiles or animals are running after him; he looks suspiciously behind the curtains or door, or under the pillow, and wants to wander about. He seldom meditates harm either to himself or others. When there is tremor, the hands are fidgetty and the patient constantly wants to use them. In addition to these symptoms are others less observed; the tongue is moist and creamy, the pulse though frequent is soft; the skin is perspiring, and emits a peculiar odour.

The disease with which this may be confounded is inflammation of the brain; and it is of the greatest importance that it should be distinguished, as the remedies that cure in the one disease will destroy in the other. Although delirium tremens does not invariably present itself in the drunkard, yet, when a person who drinks much alcohol presents many of the above symptoms, there is strong ground for believing it to be delirium tremens.

When the symptoms of this disease are obvious, its treatment is simple. The patient must have a sufficient quantity of opium administered to him to procure sleep; it should first be commenced in small doses, and then continued. A third of a grain of morphia may be given every two hours to begin with, and this may be increased to one or more grains. Generally, after a first sleep the patient becomes refreshed, and not unfrequently wakes up entirely well. Sometimes opium alone is not sufficient; this is the case where the disease has come on as the consequence of a cessation of an accustomed stimulus; in these cases it will frequently be necessary to let the patient have his ordinary beverage in order to prevent that degree of exhaustion which appears to keep up the irritability of the system. This remedy ought not, however, to be continued after the patient has acquired sufficient strength to do without it. Chloroform has been recommended as a means of procuring sleep when opium fails.

When the disease is about to terminate fatally, the delirium abates, and coma takes its place; the tremor of the limbs becomes subsultus tendinum, the evacuations are passed involuntarily, the face becomes suffused, and the patient dies as though he were in apoplexy. The attacks of delirium tremens are very apt to recur, especially in drunkards who do not after their first attack give up the vice to which they are addicted. First attacks seldom prove fatal, but subsequent attacks are not uncommonly attended with fatal symptoms. After death from delirium tremens, the ventricles of the brain are usually found effused with serum. Serum, and even lymph, is also found occasionally under the arachnoid.

(Watson, *Lectures on the Practice of Physic*; Marshall Hall, *Diseases of the Nervous System*.)

DELIVERY. [DEED.]

DELIVERY ORDER. [DOCK WARRANTS.]

DELPHINE ($C_{27}H_{19}NO_2$?). An alkaloid, not yet thoroughly investigated, found in the seeds of the *Delphinium Staphisagria*, along with a yellow solid non-crystalline body, *staphisain* ($C_{32}H_{23}NO_4$). Delphine is a light yellow resinous solid, which fuses at 248° Fahr., and volatilises with the vapour of water.

DELPHINIC ACID. [VALERIANIC ACID.]

DELPHINUS (the Dolphin), one of the old Greek constellations, referred to the fable of Amphitrite and to that of Arion. It succeeds Aquila in the heavens, and its principal cluster comes on the meridian about three-quarters of an hour later than the principal star (α) of the latter, and nearly in the same declination.

DEMAND AND SUPPLY are terms used in political economy to express the relations between consumption and production—between the demand of purchasers and the supply of commodities by those who have them to sell. The relations between the demand for an article and its supply determine its price or exchangeable value [VALUE]: the relations between the demand for labour and its supply determine the amount of wages to be earned by the labourer [WAGES]. For causes explained elsewhere, the price of an article will rarely vary, for any length of time, very much above or below its cost of production;* nor will the wages of labour, for any length of time, much exceed or fall below the amount necessary to maintain labourers and their families in such comforts as their habits of life have accustomed them to believe necessary for their subsistence; but bearing in mind that, in the prices of commodities and labour, there is a certain point, determined by causes independent of demand or supply, above or below which prices cannot materially vary for any considerable time, all variations of price, if the medium in which they are calculated remains unchanged, may be referred to the proportion which exists between the demand for commodities and the supply of them—between the quantities which purchasers are willing and able to buy, and the quantities which producers are able and willing to sell.

To have any influence upon prices, a demand must be accompanied by the means of purchasing. A demand is not simply a want—a desire to obtain and enjoy the products of other men's labour; for if this were its meaning, there would never be the least proportion between demand and supply: all men would always want everything, and production could not keep pace with consumption. But an "effective demand," as it is termed by Adam Smith, exists wherever one man is anxious to exchange the products of his own labour for that of other men. It is, therefore, of an effective demand only that political economists are speaking when they examine the circumstances of demand and supply in connection with prices.

But although a demand, without the means of purchase, cannot affect prices, the universal desire of mankind to possess articles of comfort and luxury suggests other important considerations. As this desire is natural to man, and too often is so strong as to tempt him even to commit crime, it obviously needs no encouragement: men will always gratify it whenever they have the means, and these means consist in the products of their own labour. Hence all that is required to convert this desire of acquisition into an effective demand is ample employment for industry. Increase the production of all commodities and an increased consumption of them is the certain result; for, men having larger products of their own labour to offer in exchange for the products of other men's labour, are enabled to purchase what they are always eager to acquire. Production, therefore, is the great object to be secured, not only as furnishing a supply of commodities necessary and useful to mankind, but also as creating an effective demand for them. When trade is depressed by a languid demand, it is commonly said that increased consumption is all that is required to restore its prosperity. But how is this consumption to be caused? The desire to consume is invariable, and thus any falling off in consumption must be attributed to a diminished production in some departments of industry which causes an inability to consume. When production is restored, an effective demand for all articles will immediately follow; but until the productive energies of the consumers are in a state of activity it is in vain to expect from them an increased demand.

These considerations lead us to the conclusion that a universal glut of all commodities is impossible. The supply of particular commodities may easily exceed the demand for them, and very often does exceed it; but as the constant desire to obtain commodities needs nothing but the power of offering other commodities in exchange, to become an effective demand, it is evident that a universal increase of production is necessarily accompanied by a proportionate increase of consumption. Men are stimulated by no love of production for its own sake, but they produce in order to consume directly, or because by exchanging their produce with others they are able to enjoy the various comforts and luxuries which they are all desirous of obtaining. Active production, therefore, in all departments of industry causes a general and effective demand for commodities, which will continue to be equal to the supply unless it be checked by war, by restrictions upon commerce, or by other circumstances which prevent a free interchange of commodities.

A country is in the highest prosperity when there is an active and steady demand for commodities and labour, and a sufficient supply of them. Any disturbance of the proportion between one and the other is injurious to the community; and the injury is greater or less according to the extent and duration of such disturbance. When the proportion is well adjusted, the whole community derive benefit from the circumstance, both as producers and consumers; when it is disturbed, they are injured in both capacities.

Having described thus generally the nature and causes of demand, and its intimate connection with supply, it becomes necessary to examine the influence of demand and supply upon one another, and upon production, consumption, prices, and profits. This influence varies according to the circumstances of the market, and the nature of the commodities to which its laws may be applied. These may be best understood by considering, 1st, the effects of a demand exceeding the supply; and 2ndly, of a supply exceeding the demand.

I. The first effect of a demand exceeding the supply of a commodity is to raise its price. As more persons want to buy the commodity than the producers are able or willing to supply, they cannot all obtain what they desire, but must share the supply between them in some manner. But their wants are very much regulated by the cost of gratifying them. One man would purchase an article for a shilling for which he may be unwilling or unable to pay two; while others, rather than forego the purchase, will consent to pay that amount. Those who have commodities to sell, finding that they have more customers than they can satisfy, immediately infer that they are selling them too cheaply, and that they could dispose of all their stock at a higher price. The price is accordingly raised, when the sale becomes limited to those who are not restrained from buying by the increased price. In principle, though not in outward form, the market is in the nature of an auction.

---

[*] "Cost of production" is used by political economists in a sense different from that of commerce, and includes profits. (See M'Culloch's edition of Adam Smith, c. 7.) It means, in fact, the price below which no man would continue to sell his goods. An ordinary profit is a part of the cost of production in an enlarged sense, as much as the expense of wages and materials.

The sellers endeavour to obtain the highest price for their goods; the price rises with the eagerness of those who wish to buy, and the highest bidders only secure the prizes. In the market, however, the competition of the buyers is not perceptible amongst themselves except through the prices demanded. Their competition determines the prices, but the sellers judge of its extent and regulate their demands so as to obtain the greatest possible advantage from it.

Some commodities are positively necessary for the support of the people, of which the supply may fall very short of the demand and be incapable of increase. This is the case when there is a bad harvest in a country which is excluded from a foreign supply by war or by fiscal restrictions. Here the price rises in proportion to the deficiency of the crops. The competition for food is universal. Some, indeed, may be driven to the consumption of inferior articles of food, and others to a diminished consumption; but all must eat. The number of consumers is not diminished, while the supply is reduced; and the price must, therefore, rise and continue high until a fresh supply can be obtained. In a siege the competition is still greater: the prices of provisions become enormous; the rich alone can buy, the poor must starve or plunder.

A similar effect is produced if the supply, without being deficient, be confined to the possession of a small number of persons, who limit it to the consumers in order to secure higher prices. However abundant corn might be in a besieged town, if one man were exclusively authorised by law to sell it, it might rise to a famine price, unless the people broke into the granaries, or the government interfered with the monopoly. Less in degree, but similar in principle, is the effect upon prices of every limitation of the market by fiscal restrictions. When any sellers are excluded, the others are enabled to raise their prices.

These are cases in which the supply cannot be increased to meet the demand, or in which the supply is monopolised. But the greater number of commodities may be increased in quantity, and the supply of them is not artificially limited. The price of these also rises when the demand exceeds the supply; but the increased price raises the profit of the producer and attracts the competition of others in the market. Fresh capital and labour are applied to the production of the profitable article, until the supply is accommodated to the demand, or exceeds it. The prices gradually fall, and at length the profits are reduced to the same level as the profits in other undertakings, or even lower. The encouragement to further production is thus withdrawn, and prices are adjusted so as to secure to the producers the ordinary rate of profits, and no more.

But sometimes the demand for a commodity is diminished, if the supply fall short of it for any considerable time. There are various articles useful and agreeable to mankind, but not essential to their existence, which they are eager to enjoy as far as they can, but for which they are not prepared to make great sacrifices. When the price of an article of this description is raised by a deficient supply, continuing for some length of time, it is placed beyond the reach of many persons, who learn to regard it with indifference. They would buy it if it were cheap; but as it is dear they go without it, or are satisfied with a substitute. In this manner the number of consumers is diminished. Others again, who will not be deprived of an accustomed luxury, enjoy it more sparingly, and consume it in less quantities. But so long as the supply is not increased, the price will continue high, because the consumers who still purchase the article, notwithstanding its price, keep up an effective demand equal to the whole supply; while there is still a dormant demand, only awaiting a reduction of price to become effective.

For the same reasons, a demand for articles is diminished when their price is artificially raised by taxation. The demand is gradually confined to a smaller number of persons, and many consume more sparingly. [Tax; Taxation.]

In these various ways demand and supply become adjusted through the medium of price, whenever the one exceeds the other. This is the result of natural laws, the operation of which is of the highest value to mankind. If the supply be incapable of increase, it economises consumption; if the supply can be increased, it encourages production. In either case it is of great benefit to the consumer. To revert, for a moment, to the example of a bad harvest in a country excluded from all foreign supply. Suppose that prices did not rise, but remained precisely the same as if the harvest had been abundant, what would be the consequence? The whole population would consume as much bread as usual, and use flour in every way that luxury points out, unconscious of any scarcity. Farmers might even feed their cattle with wheat. By reason of this improvidence, the whole of the corn would be consumed before the next harvest, and the horrors of famine would burst, without any warning, upon a people living as if they were in the midst of plenty. This evil is prevented by a rise of prices, which is a symptom of scarcity, just as pain is a symptom of disease. By timely precaution the danger is averted. A high price renders economy and providence compulsory, and thus limits consumption. The supply, therefore, instead of being exhausted before the next harvest, is spread over the whole year. In the case of food, it is true that such economy is painful, and presses heavily upon the poor; but this evil is a mercy compared with famine. If no privation had been endured before scarcity became alarming, none but rich men could buy a loaf; for every one who had a loaf to sell would be risking his own life if he sold it.

These observations are also applicable in some measure to cases in which prices are raised by the supply being confined to one or to a few persons, who have contrived to buy up the whole or nearly the whole of any commodity. But such exclusive possession (sometimes improperly called a monopoly) cannot exist for any length of time in articles of which the supply is capable of increase. The extreme case has been put of a besieged town in which the whole supply of corn was monopolised by one man. Under those circumstances, of course he would demand a high price; but unless his exclusive supply were upheld by law, it does not follow that the inhabitants would suffer on that account. A most provident consumption of food is absolutely necessary for the defence of a town, and no organisation could distribute provisions according to the wants of the people so well as a system of purchase restrained by a high price. It must also be recollected that, without any such exclusive possession, the fact of the siege alone must raise prices by cutting off fresh supplies. If the siege continue, provisions are more likely to last out by the instrumentality of prices than by any other means. At the same time the sole possessor of the corn would be restrained from keeping back the supply beyond the actual necessity of the occasion by many considerations. He would know that if a popular tumult arose, if the town were relieved, the siege raised, a capitulation agreed to, or the place suddenly carried by assault, the value of his exclusive property would be destroyed. His own interest, therefore, is coincident with that of the people. It is better for both that the supply should be meted out with parsimony; it is dangerous to both that it should be immoderately stinted.

In circumstances less peculiar than these, very little evil can arise from an exclusive possession of any commodity not protected directly or indirectly by law. If the supply be capable of increase, and the demand be sufficient to enable the owner to secure a high price, for reasons already explained, the market would rapidly be supplied from other quarters. If the supply cannot be increased, that fact alone would raise the price; and it is probable that the supply would not have been so great without the extraordinary activity of the capitalist, who had been able to secure for his country the whole accessible supply to be collected from the markets of the world.

A monopoly, properly so called, is of a totally different character; for however abundant the supply of an article may be, it may, nevertheless, be inaccessible to the consumer. [Monopoly.] Such monopolies were properly condemned so far back as the reign of James I. (21 James I. c. 3), although vast monopolies are still indirectly maintained by our fiscal laws. [Tax; Taxation.] The legislature of this country, however, did not observe any distinction between a legal monopoly and the great speculative enterprises of commerce, miscalled monopolies; and severe penalties were inflicted, both by the common and statute laws, against offences called "badgering, forestalling, regrating, and engrossing." The impolicy of such laws was gradually perceived. If prices were occasionally raised by speculations of this kind, yet the restraints upon commerce, which resulted from these laws, were infinitely more injurious to the consumer. Many of the statutes were therefore repealed by Act 12 Geo. III. c. 71; but the common law, and all the statutes relating to the offences of forestalling, regrating, and engrossing, were not erased from our commercial code until the year 1844 (Act 7 & 8 Vict. c. 24).

When prices are high by reason of the demand exceeding the supply, it is by no means necessary that the profits of those who sell the dear commodities should always be greater than the profits in other branches of trade. It must always be recollected, that where scarcity is the cause of high price, the sellers who demand it have the less to sell. Where scarcity is not the cause, but the demand is great because the supply, notwithstanding the exertions of the producers, cannot keep pace with it, the profits are undoubtedly greater than usual, until the supply has been increased.

II. It is now time to consider the effects of a supply exceeding the demand; and this division of the inquiry will require less elucidation, as the effects of such a condition of the market may be stated to be the very reverse of those which we have just been examining. When there is more of a commodity than people are prepared to buy, its price must fall. Its sellers must offer it for sale at the price at which they can induce people to purchase. All is now in favour of consumers. They are no longer bidding against each other: but the sellers are competing among themselves to get rid of their goods. The price falls generally in proportion to the excess of the quantity, but this result is very much qualified by the nature of the article. If there be an excess of supply in perishable goods, there is nothing to prevent the natural fall of prices. When fish is unusually abundant, it must be cheap, or a great part of it will be destroyed: it must be eaten at once, or not at all; and to induce people to eat it, it must be offered to them at a low price. But with articles which may be held back, in expectation of higher prices, their value may be partially sustained. Production may be reduced, and the stock gradually brought into the market, until the supply has been equalised with the demand; and wherever the article is such as to admit of voluntary increase or diminution, the natural result of an excessive supply is to reduce production, until the balance of supply and demand has been restored. This mutual adjustment is in perpetual operation, and is ordinarily effected with such precision, that it may be said, without exaggeration, that a large city is supplied exactly with everything its inhabitants require—even down to an egg or a pint of milk. There is always enough of everything, and rarely too much.

Whenever there is an excessive production of any commodity, it is an evil almost as great as scarcity. It is true that the consumer derives benefit from it, but the producing classes are most injuriously affected. In order to raise the value of the produce of their labour, they must cease to produce, or must produce in less quantities. The workmen are thus either deprived of employment altogether for a time, or are employed for a portion of their time only, at reduced wages; while their employers are disposing of their goods at low prices, which scarcely repay the outlay of their capital. Nor does the penalty of over-production fall exclusively upon those engaged in the trade in which supply has exceeded the demand. Their distresses extend to other classes. It has been shown already that it is to production we must look as the cause of sustained consumption, and thus the pressure upon any considerable branch of productive industry must be sensibly felt by those who have the produce of their own labour to sell. Production has failed, and consumption must therefore be diminished.

The ruinous consequences of gluts, in particular staples of trade and manufacture, are too well known, especially in this country, to require any further illustration; but their causes are not always agreed upon. Such gluts are often attributed to the facility with which manufactures are produced by machinery; but we have shown that over-production in all branches of industry is impossible, and if that be true, it is evident that when partial gluts are produced by the aid of machinery, that powerful agent must have been misapplied. It is not contended that nothing can be produced in too great abundance. Whether machinery be used or not, production must be governed by the same laws of demand and supply. Those things only must be produced for which there is a demand, and they must not be produced in greater abundance than the demand warrants. But the more generally machinery is used, the more abundant will be the products which men will have to exchange with each other, and therefore the better will be the market. It follows that machinery can only cause a glut when applied excessively to particular objects, precisely in the same manner as an excessive quantity of labour would cause one if applied where it was not needed by the demands of commerce.

The supply of markets is a very speculative business, and is often conducted with more zeal than discretion. When a particular trade is supposed to be more prosperous than others, capitalists rush into it in order to secure high profits; and in this country the abundance of capital, the perfection of our machinery, and the skill of our workmen, enable them to produce with extraordinary facility. Over-production in that particular trade is the consequence, and all engaged in it suffer from the depreciation in the value of their goods; but if, instead of rushing into the favourite trade, they had distributed their enterprises more widely, their own interest and that of the community would have been promoted. When a ship is wrecked, if all the crew precipitate themselves into one boat, they swamp it; but if they wait till all the boats are lowered, and apportion their numbers to the size of each, they may all reach the shore in safety. And so it is in trade: one trade may easily be glutted, while there is room in other trades for all the capital and industry that need employment.

In proportion to the extent of the market and the variety and abundance of commodities to be exchanged, will be the facility of disposing of the products of capital and labour; and this consideration points out as the most probable antidote to gluts a universal freedom of commerce. When the free interchange of commodities is restricted, not only is a glut caused more easily, but its causes are more uncertain, and dependent upon unforeseen events. With the whole world for a market, the operation of the laws of demand and supply would be more equable, and the universality of the objects of exchange would make gluts of rare occurrence. The market would still be liable to disturbance by bad harvests, by errors in the monetary system, by shocks to public credit, and by war; but apart from these causes of derangement, demand and supply would be adjusted, and the productive energies of all nations called into full activity.

DEMESNE. [MANOR.]

DEMETER (Δημήτηρ), one of the twelve principal deities of the Olympus of the Greeks: by the Romans she was called Ceres. Demeter was the great mother-goddess, the giver of the fruits of the earth, the nourishing and fertilising principle of nature.

In the Greek mythology Demeter was the daughter of Kronos and Rhea. By her brother Zeus she was the mother of Persephone (often only called Cora, Κόρη, the maiden, the Proserpine of the Romans), and also according to Hesiod (Theog. 452, &c.), of Dionysus (Bacchus); but the more prevalent notion was, that Dionysus was the son of Semele. It is certain, however, that Demeter is in various ways closely associated with Dionysus, and their rites, the Dionysian and Eleusinian mysteries particularly, as will be noticed further below, are intimately blended. By later writers, Demeter is sometimes alluded to as the wife of Dionysus.

The leading feature in the story of Demeter, and that which forms the fundamental idea of her worship, is the loss and recovery of her daughter, Persephone, who was suddenly seized and carried off to the infernal regions by Pluto [PERSEPHONE]. Demeter, who heard her cries, but did not see who had carried her away, nor know whither she had gone, sought in vain for her over the earth, till she applied to Helios. Having learned from him that Zeus had, without consulting her, given Persephone to Pluto as his wife, and that she had been carried off to Erebus, Demeter in her anger vowed not to return without her to Olympus. Zeus sent first Iris, and then all the gods to invite her to return, but in vain; when fearing lest the human race should perish, she having afflicted the earth with sterility, he despatched Hermes to Erebus to bring back Persephone. Pluto did not offer to resist the will of Zeus, but he gave Persephone a pomegranate, and she having eaten of the food of Erebus was thenceforth compelled to spend a portion of every year in the infernal regions. Hermes conducted Persephone to her mother at Eleusis, and Zeus sent Rhea to again urge Demeter to revisit Olympus, informing her that he had consented that Persephone should remain with her mother two-thirds of the year, the other third (the season of winter) being spent with Pluto. Demeter now consented to return, and to restore fertility to the earth. But before departing from Eleusis, which she had made her abode, she taught Triptolemus the manner in which her worship was to be conducted, and instructed him in the mysteries of the Eleusinia. [ELEUSINIA.]

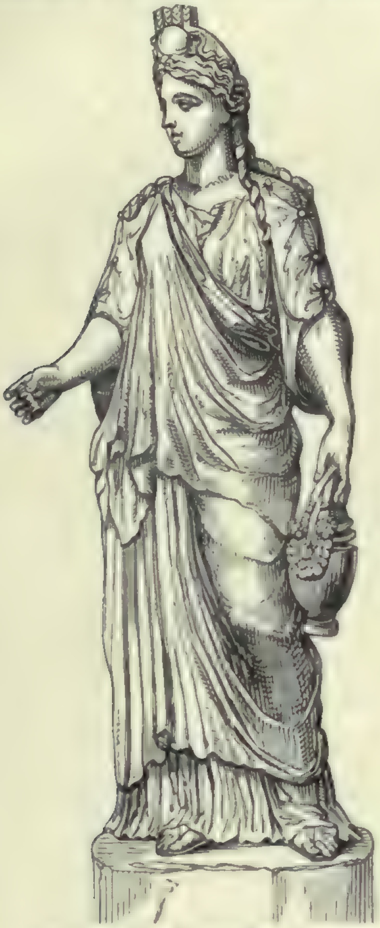
Demeter was the oldest, and with a view to the formation of a systematic mythology, the most important personage in the Greek polytheism. Her name Demeter (*γῆ, earth, μήτηρ, mother*), or Deo, points to her as a representative of the earth and its productions in the old elementary worship of Greece; and she is invoked by Orpheus (apud Diod. Sic. i. 12) as Mother Earth, the giver of all sorts of riches (*γῆ μήτηρ πάντων Δημήτηρ πλουτοδότειρα*). The title Father is in the same manner given to the air by Lucretius (i. 25),

> Postremo pereunt imbres ubi eos *pater Æther*
> In gremium *matris Terrai* præcipitavit;

and the Greeks considered all vegetable productions as the offspring of a union between these two elements. (See the fragment of the Danaides of Æschylus in Hermann's 'Opuscula,' vol. ii., p. 334.) The mystic union of these two principles, from which all the other deities sprung up, is an invention of the later philosophers. A remarkable feature which the worship of this deity presents in Greek mythology is her intimate connection with Dionysus, a connection which seems to have belonged to all the different modifications of the two worships. At Eleusis these two deities were worshipped with peculiar solemnities. [DIONYSIA, ELEUSINIA.] It does not seem right to infer from the similar relation subsisting between Osiris and Isis in Egypt, and Dionysus and Demeter in Greece (Macrob., 'Saturnal.,' i. 2, p. 210; Herod. ii. 144; Plutarch 'de Iside,' p. 354 F.), that the worship of these deities was derived from Egypt, in particular, though, as will be seen by the engraving below, Demeter was sometimes represented by the ancient sculptors with some of the attributes of Isis. Still less, however, can we adopt Creuzer's theory of the Indian origin of this religion. It seems more reasonable to conclude that the same causes which might contribute to produce such an elementary worship in the East would have the same effect in Greece; for the constitution of the human mind is much the same in all parts of the world.

A collection of the names and epithets of Demeter is given by Creuzer ('Symbolik,' vol. iv., p. 301, fol.), but his remarks must be read with some caution, as he shows a curious readiness to identify her with other deities. The meaning of her Roman name, Ceres, by which Demeter is generally mentioned in English books on mythology, is not known; it may be derived from *c(e)reare, creare*, to produce (Creuzer, 'Symbolik,' iv., p. 313); or it is connected with her Cabiric name, Axiokersa, in which case it also signifies the producer; for according to Hesych., *κέρσαι = γαμῆσαι, κέρσης = γάμος* and *μίξαι = κέρσαι*.

Demeter is represented in ancient monuments with a basket (*κάλαθος*), or a crown of ears of corn on her head, with some ears of corn and poppies in her right hand, and a torch, or occasionally a sceptre, in her left hand, and sometimes as seated in a chariot drawn by lions, panthers, elephants, or dragons. (Winckelmann's Works, vol. ii. 515, iv. 119.) Her form is that of a beautiful matronly woman, with a mild and benevolent expression of face. She is always enveloped with ample drapery, which is usually close up to the neck; but sometimes one of her teeming breasts is uncovered. Demeter is frequently seen enthroned, or seated with her daughter Persephone alongside of her; the figure of Persephone being much slighter and less matronly than that of her mother. Two very beautiful figures on low seats, from the Western pediment of the Parthenon at Athens, and now in the British Museum, are believed to represent Demeter and Persephone, but both the figures have lost their heads, and their distinguishing attributes. A fine statue of the Græco-Roman period, in the same collection (from the Macarani Palace at Rome), of which we give a cut, represents the goddess with some of the attributes of Isis, but the head appears to have belonged to another statue of Ceres. It is in the head that the Egyptian character is discernible. On it is an Egyptian diadem, in front of which is a disc between two serpents, and surmounted with ears of corn. She wears a long tunic and pallium; and holds in her left hand a *situla*, or sacred bucket, and wreaths of flowers; the right hand is a modern restoration. Demeter is sometimes represented (especially on gems and vases) as an enraged deity, with torch in hand and flying drapery searching after the lost Persephone. Sometimes, again, escorting her daughter on her annual journey to or from Erebus. Among other of the less familiar events in her story, which appear to have often engaged the skill of the Greek sculptors and vase-painters, was her connection with the mystic Iacchus, who is represented sometimes as a child at her breast, sometimes as a boy beside her. A colossal bust crowned with a basket, which is believed to have been a portion of the great statue of Demeter, was, in 1801, brought from the site of the chief temple of the goddess on the Acropolis of Eleusis, and deposited in the public library of Cambridge University; but it has been by some supposed to have rather formed a portion of a canephorus or cistophorus. The great temple of Demeter at Eleusis was the largest in all Greece, and was designed by Ictinus, the architect of the Parthenon. Very little is now left of it; its area forming the centre of the modern village. [ELEUSIS, in GEOG. DIV.]



[Demeter, from the British Museum.]

DEMI-LUNE. [RAVELIN.]

DEMISEMIQUAVER, a musical character, formed by adding three hooks to the stem of a crotchet, Ex.—

and in length, or duration, is equal to $\frac{1}{32}$ of a semibreve. [SEMIBREVE.]

DEMOCRACY (*δημοκρατία*) a word taken from the Greek language, like aristocracy, oligarchy, monarchy, and other political terms.

The third book of Herodotus (chap. 80-82) contains what we may consider as the views of the oldest extant Greek historian on the merits and defects of the three respective forms of government as they are called, democracy, oligarchy, and monarchy. It would be difficult to extract from the chapters referred to an exact definition of democracy, but still we learn from them what were considered to be essentials; first, complete political equality (*ἰσονομίη*); secondly, the election of magistrates by lot (*πάλῳ*) (which, coupled with the first condition, implies that public offices must be accessible to all); thirdly, responsibility or accountability in public functionaries (*ἀρχὴ ὑπεύθυνος*), which implies a short term of office and liability to be ejected from it; fourthly, the decision by the community at large of all public matters (*τὸ βουλεύματα πάντα ἐς τὸ κοινὸν ἀναφέρειν*).

It is unnecessary to mention the merits and defects of a democracy as pointed out in the above chapters, the defects being only certain consequences supposed to flow from, and the merits certain advantages incident to, a democratical institution, and neither being essentially parts of the fundamental notion of a democracy.

In forming a notion of a democracy as conceived by the Greeks, and indeed in forming any exact notion of a pure democracy, it is necessary to consider a small community, such as a single town with a little territory, and to view such a community as an independent sovereignty. The institutions which in modern times have approached most nearly to the form of a pure democracy are some of the Swiss cantons. The boroughs of England, as existing in their supposed original purity, and as partly restored to that supposed original purity, by the Municipal Corporation Act, may help to explain the notion of a democracy, though they are wanting in the necessary element of possessing sovereignty. Further, to conceive correctly of a Greek democracy and of some of the democracies of the North American Union, it must be remembered that the whole community in such States consisted and consists of two great divisions, freemen and slaves, of whom the latter form no part of the political system.

In most Greek communities we find two marked divisions of the freemen, the "few" (*ὀλίγοι*) or "rich" (*δυνατοὶ, πλούσιοι*), and the "many" (*οἱ πολλοὶ, ὁ δῆμος*) or "not rich" (*ἄποροι*), between whom a fierce contest for political superiority was maintained. This contest would often end in the expulsion of the "few," and the division of their lands and property among the "many;" sometimes in the expulsion of the leaders of the "many," and the political subjugation of the rest. Thus the same state would at one time be called a democracy, at another an oligarchy, according as one or the other party possessed the political superiority; a circumstance which evidently tended to confuse all exact notions of the meaning of the respective terms used to denote the respective kinds of polities. Under the circumstances described, what was called an oligarchy might perhaps be appropriately so called; what was called a democracy was not appropriately so called, even according to the notions entertained by the Greeks themselves of a democracy; for such so-called democracy was only a fraction of the community that had obtained a victory over another fraction of the community, less numerous and individually more wealthy: for the "few" and the "rich" were necessarily united in idea; it being, as Aristotle remarks, incident to the "rich" to be the "few," and the rest to be the "many."

Aristotle felt the difficulty of defining what a democracy is. He observes ('Politik.' iv. 4) that neither an oligarchy nor a democracy must be defined simply with reference to the number of those composing the respective bodies: if a considerable majority, he says, are rich, and exclude the remaining body of freemen, who are poor, from political rights, this is not a democracy. Nor, on the contrary, if the poor, being few, should exclude the rich, being more numerous, from all political power, would this be an oligarchy. Indeed such a supposition as the latter is impossible in a sovereign community, except during a short period of revolutionary change.

Aristotle, after some preliminary remarks, concludes by defining a democracy to be, when the freemen and those not the rich, being the majority possess the sovereign power; and an oligarchy, when the rich and those of noble birth, being few, are in possession of the sovereign power. This definition of an oligarchy necessarily implies that the majority are excluded from participating in the sovereign power. It might be inferred, on the other hand, that in this definition of a democracy the few are excluded from the sovereign power; and such in this passage should be the meaning of the author, if he is consistent with himself. In another passage (iv. 4), where he is speaking of the different kinds of democracy, he speaks of the first kind as characterised by *equality* (*κατὰ τὸ ἴσον*): and by this equality he understands "the not rich having no more political power than the rich, neither body being supreme, but both equal, and all participating equally in political power." Such in fact approached very near the exact notion of a pure democracy, or at least a democracy as pure as we have any example of; for women, persons of unsound mind, males not adult, and slaves, are excluded from political power even in democracies.

A pure democracy, then, is where every male citizen, with the exceptions above mentioned, forms an equal and integral part of the sovereign body; or, as Aristotle expresses it, the democracy is "monarch, one compounded of many." This is the fundamental notion of a democracy: every other institution incident to or existing in a democracy, is either a necessary consequence from this notion or a positive law enacted by the universal sovereign.

If the democracy consider a constitution [CONSTITUTION] to be useful for carrying into effect the will of the sovereign, such constitution, when made by the expressed will of the majority, whatever may be the terms of such constitution, does not affect the principle of the democracy. Such constitution can be altered or destroyed by the same power that made it. If a representative body is necessary for effecting the purposes of the sovereign, such body may be elected and invested with any powers by the sovereign body, always provided that the representative body is responsible to the sovereign whose creature it is. Whatever institutions are created, and whatever powers are delegated by the sovereign many, the principle of pure democracy still exists so long as every individual and every body of individuals who exercise delegated power are responsible to the sovereign body by whom the power is delegated. Hence if property be made a qualification for certain offices, as in one of the forms of democracy mentioned by Aristotle, by the universal sovereign, such requisite qualification does not in itself alter the nature of the democracy, being only a rule or law fixed by the sovereign. It is, however, a rule or law of that class, the *tendency* of which, where the sovereign power is possessed by the many, is to undermine and ultimately destroy the power that made it.

Experience has shown that even where the universal people are sovereign, if the political community is large and spread over a great surface, every delegation of power, however necessary, is accompanied with danger to the existence of the sovereign power. The more complicated the machinery of administration becomes, and the more numerous are the administering bodies interposed between the sovereign and the accomplishment of the object for which the sovereign delegates part of his power, the greater is the risk of those who have had power delegated to them making themselves the masters of those who have conferred the power. In a democracy the great problem must be to preserve unimpaired and undisputed the vital principle of the sovereign power being in all and in every individual, and to combine with this such a system of delegated powers as shall in their operation always recognise that principle to which they owe their existence.

Aristotle ('Pol.' iv. 5) well observes that a polity may not be democratic according to the laws, that is, the fundamental laws or constitution, but that by opinion and usage it may be administered democratically: in like manner a democratic constitution may come to be administered oligarchically; and he explains how this may come to pass.

It may happen that other persons besides those enumerated may be excluded from participation in the sovereign power in a government which is called a democracy. The suffrage may be given only to those who have a certain amount of property, which resembles one of the cases mentioned by Aristotle. If the amount of property required should exclude a great number of the people, the government might still be called democratical rather than by any other name, if the persons excluded were a small minority compared with the majority. If they were nearly equal in numbers to the majority, they would find out some name for the majority which would express their opinion of the form of government: and the word that they would now use would be aristocratical, a word which would imply dislike and censure. If the portion of the people who were thus excluded from the suffrage should be a majority, the ruling body would be properly called an aristocracy.

A democracy has been here defined as it has existed in some countries and as it exists in others. No attempt is made to ascertain its origin, any more than the origin of society. It is here viewed as a form of government that may and does exist. The foundation of the notion of a democracy is that the sovereign power is equally distributed, not among all the people in a state, but among all the freemen who have attained a certain age, which is defined. Democracy therefore, if we derive the notion of it from all democracies that have existed, instead of from certain wild theories of natural rights, is based upon the principle that it is for the general interest that some persons should be excluded from the possession of that political power which others enjoy. A democracy also like a monarchy can only give effect to its will through the medium of forms and agents. Practically there cannot always be a reference to the will of the majority on every occasion, no more than there can be in a monarchy. A monarch must govern by the aid of others, and the sovereign democracy must carry its purposes into effect by the aid of members of its body, to whom power sufficient for the purpose is given. The agent of a democracy is a representative body for the purpose of legislating. For the usual purposes of administration a democracy must have agents, officers, and functionaries, as well as a monarchy. The mode in which they are chosen and the tenure of office may be different, but while they act, they must have power delegated of a like kind to that which a monarch delegates. A form of government may be such that there shall be an hereditary head, a class with peculiar privileges, and also a representative body. The existence of a representative body chosen by a large class of the people, has led to the appellation of the term democratical to that portion of such governments which is composed of a representative body, and to those who elect such body. But the use of the terms democracy and democratical, as applied to such bodies, tends to cause confusion. It is true that such mixed governments present the spectacle of a struggle between the different members of the sovereign power, and as it is often assumed that the popular part aims at destroying the other parts, and as many speculators wish that it should ultimately destroy them, such speculators speak of such so-called democracy as a thing existing by itself, as if it were a distinct power in the state; whereas, according to the strict notion of sovereignty, there is no democracy except when there is no other power which participates in the sovereignty than individuals possessed of equal political power. When the popular member of a sovereign body has destroyed all the other members, the popular member becomes the sovereign body, and it is a democracy, if it then corresponds to the description that has been given of a democracy.

A curious article by M. Guizot, entitled 'Of Democracy in Modern Society,' has been translated and published in England. It is written with reference to the condition of France, and in opposition to the assertion made by some French writers "that modern society, our France, is democratical, entirely democratical; and that her institutions, her laws, her government, her administration, her politics, must all rest on this basis, be adapted to this condition." M. Guizot successfully combats certain hypotheses and assumptions, most of which however have either been exploded by all sound political writers or would be rejected by any man of reflection. His essay contains, as we might expect from his attainments and long experience in the world, many just remarks, but it is disfigured and often rendered almost unmeaning by the lax use of political terms and a tone of mysticism and obscurity which are better adapted to confuse than to convince.

In the third volume of 'Political Philosophy,' published in 1846, Lord Brougham has treated the subject at considerable length, and illustrated it with examples which fully support the views given above.

DEMOIVRE'S HYPOTHESIS. An hypothesis on the duration of human life, formed by Demoivre, as he informs us in the preface of his 'Treatise on Annuities,' some years after the publication of the first edition of his 'Treatise on Chances,' on the inspection of 'Halley's Breslau Tables.' Observing that the decrements of life at the middle ages were very nearly uniform, Demoivre made an extension of this law to the whole of life, not thereby intending to assert that any such principle was correct for childhood and old age, but simply that the effect of the error upon the value of annuities at the middle ages of life would be trivial. The hypothesis is as follows: *of eighty-six persons born, one dies every year, till all are extinct.* The remainder of eighty-six years, at every age, Demoivre called the *complement of life.* The half of the complement of life is the average duration (commonly called the expectation); and the peculiarity of Demoivre's hypothesis is, that, according to it, every person has an even chance of living the average time of people of his age, which is not true of other tables. The Northampton Tables certainly do nearly coincide with this law at the middle periods of life, but the Carlisle and most other tables differ materially from it. Thus at twenty years of age, according to the Carlisle Tables, the *average duration* is to the age of sixty-one and a half, while each individual aged twenty *has an even chance* of living to be about sixty-five years of age.

The following table (left hand) shows the number of persons out of ten thousand who may be expected to die in the year next following their attaining the age marked in the first column, according to this hypothesis, the Northampton and Carlisle Tables, and the Belgian Tables of M. Quetelet:—

Age.	Hypothesis.	Northampton.	Carlisle.	Belgian.
10	132	92	45	88
20	152	140	71	120
30	179	171	101	136
40	217	209	130	144
50	278	284	134	183
60	385	402	335	325
70	625	649	516	680
80	1667	1343	1217	1425

Age.	Hypothesis.	Northampton.	Carlisle.
10	19·9	20·7	23·5
20	18·5	18·6	21·7
30	16·8	16·9	19·6
40	14·8	14·8	17·1
50	12·5	12·4	14·3
60	9·7	9·8	10·5
70	6·4	6·7	7·1
80	2·3	3·8	4·4

The right hand table shows the values of annuities on lives of the ages in the first column, at three per cent., in years' purchase. Practically speaking, then, the celebrated Northampton Tables agree with Demoivre's hypothesis in their money results, though by no means exhibiting the same physical law of life.

It must be observed of Demoivre's hypothesis, that any one which supposes uniform decrements throughout is entitled to the name, whether the limit of life be eighty-six years or not. Conformably to this view, the modification which best represents the Carlisle Tables would be, that, of 128 persons born, one dies every year; a supposition which would be as much in excess on one side, for old lives, as that of eighty-six is in defect, but which would represent the Carlisle Tables from twenty to fifty years of age as well as the use of eighty-six does the Northampton Tables.

DEMOLITION of works, buildings, &c. The method to be employed in the destruction of works, buildings, bridges, &c., by gunpowder in war time, being so much dependent on the amount of labour and time which can be employed on it, and the fact that no certain rules have yet been arrived at for determining the proper charges for throwing down masonry, make the military engineer dependent on his own judgment, and a consideration of some of the examples of demolitions which have been successful, but at the same time render the subject too diffuse to be more than hinted at in such an article as the present; the reader being referred for details of the subject to the article 'Demolition,' by Gen. Sir H. D. Jones, R.E., in the 'R.E. Aide-Mémoire.' The works which a military engineer is principally called upon to destroy are, revetments, towers, magazines, military buildings, bridges, and barriers.

Revetments have been destroyed in a variety of ways, either by piercing the foot of the revetment from the ditch, or by sinking shafts at the back of the revetment, or by running galleries from the interior of the work to the back of the revetment, the employment of either of these means being dependent on the circumstances of the nature of the revetment, and of the soil of the rampart. In the destruction of the Spanish lines before Gibraltar in 1810, several attempts were made to run a gallery from the interior of the work to the back of the revetment, but the sand so constantly came in at the head of the gallery, that it at last brought down the terreplein, and eventually shafts had to be sunk at the back of the revetment, which is in general the commonest and easiest method of execution. When the shaft or gallery has been driven to the foot of the revetment, short returns are usually made to the right and left along the back of the revetment, and the charges either placed against or in the counterforts, or disregarding them, as at the destruction of the face of a bastion at Turin, which was successful at equal distances along the revetment. Gen. Sir Charles Pasley, in his tract on 'Military Mines,' gives $\frac{3}{20}$ LLR³ [MINES], as the charge when placed at 2-lined intervals along the back of the revetment without counterforts, $\frac{1}{5}$ LLR³, when in the middle of each counterfort at its junction with the revetment, and $\frac{1}{3}$ LLR³ when in the centre of a line of masonry with counterforts at 2-line intervals, whilst $\frac{1}{10}$ LLR³ is the charge when placed in the centre of a mass of masonry of a circular or polygonal base.

Towers are usually destroyed either by mining the base, as with revetments, or by placing the charge in the centre of basement on the floor, or distributing at the angles of the basement.

Magazines, if time will permit, are best destroyed by a series of mines placed in the centre of the thickness of its piers and of its gable; but they may be hastily destroyed by placing the powder in a heap on the floor, fastening the doors and windows, and firing by a hose from the outside.

Buildings may be destroyed by charges placed in the same way in the cellars or lower rooms, or by placing a series of small charges or blasts in the thickness of the wall of the basement between the windows, the holes being driven from the windows.

Various methods were adopted in the Peninsula war for destroying bridges, according to circumstances. It frequently happens whilst an army is before the enemy, and closely pressed by him, that a bridge is required to be destroyed to prevent his pursuing a retreating body, or to gain time for the movements of an army by arresting his progress. Sir H. Jones says in the article before mentioned, "In the retreat of the British army from Burgos, upwards of twenty bridges were destroyed, with the exception of two or three, which were only partially injured from want of time; the destruction of the others was perfect; in many cases the train was not lighted until the enemy were actually on the bridge; in others, as at Cabezon, the enemy's pickets were two or three days at one end of the bridge; an officer of engineers, during that time, waiting with a lighted slow match, prepared to fire the train the instant the enemy should attempt to push on to the bridge; at the same time cautioned not to be deceived by false alarm of his advance. In many instances an officer of engineers was unexpectedly called upon for the duty of destroying a bridge, sent off at a moment's notice forty or fifty miles, to be followed by a muleteer carrying two barrels of powder; without a miner or tools, other than what could be collected in the neighbourhood of the bridge to be destroyed, and with such assistance in manual labour as could be procured on the spot, or by the assistance of some of the dragoons forming his escort." The fate of the campaign may depend on the proper execution of this duty. The following modes are usually adopted: 1. By sinking a shaft in the roadway, generally a few feet to the right or left of the centre of the width of the bridge, down to the haunch of the arch, with a very short gallery ending in a chamber, so as to lodge the powder in the middle of the width of the bridge under the roadway. If the charge is to remain for some time, care must be taken to secure it and the hose or train from damp and injury by traffic over the bridge. 2. When the bridge is very wide, by sinking two shafts and placing two charges of powder—though this method is liable to failure by one charge only exploding, and leaving half the bridge standing. 3. Laying a quantity of powder on the crown of the arch, so as to break it down by the concussion; the French say 100 lbs. are sufficient for this; it is however doubtful. 4. Suspending the charge under the crown of the arch. 5. Driving a gallery into the pier at the springing of the arch, which would be a good plan but for the difficulties attending its execution. "At Duenas in 1812, on the retreat from Burgos, the rear guard of the army was closely pressed by the enemy; the bridge was of solid masonry from the arch to the roadway; the miners had only time to strip off some of the pavement, and lodge two barrels of powder in the hole, covering them as hastily as possible with the small quantity of material at hand: when fired, the effect was to break down the entire breadth of the arch, making a gap of 15 feet." Barriers were formerly destroyed by the petard, this, however, is a clumsy instrument to carry about, and at the present day a bag of powder of about 60 to 100 lbs. is generally all that is found necessary. If suspended or laid against the barrier or gate its explosion is generally found to be effectual, as at the late siege of Delhi, and at Ghuznee in 1839, where, however, 300 lbs. in twelve sand-bags was used.

DEMONSTRATION. The old use of this word is as follows: It meant any manner of *showing* either the connection of a conclusion with its premises, or that of a phenomenon with the asserted cause. Thus we find it asserted by an early writer that the system of Copernicus, *though false*, gave *truer* demonstrations of the celestial motions than any other: meaning that those motions could be more easily shown to be a necessary consequence of the hypothesis cited than of any other. It is very important, in reading the old English writers, to remember this use of the term.

Demonstration now means only that process by which a result is shown to be a necessary consequence of the premises from which it is asserted to follow, on the supposition that those premises are admitted, either as matter of fact, or of intuitive evidence, or of previous demonstration. Thus the 47th proposition of the first book of Euclid demonstrates a certain property of a right-angled triangle, on the supposition 1, that all the preceding propositions are true; 2, that the axioms used in geometry, whether expressed or implied, are true also. It makes the consequence as certain as the premises, by means of the indubitable character of the connecting process. This strict use of the term demonstration belongs to the science of logic, which contains the art of demonstrating from premises, without reference to the truth or falsehood of the premises themselves.

But in common life the word demonstration means any sort of reasoning which the party using the term chooses to call proof. "I consider it as demonstrated," means the same thing as "evidence has been offered which makes it so probable to me that I am willing to act upon that evidence." Most minds have no idea of a middle state; they either absolutely receive or absolutely reject: so that in fact demonstration comes with any degree of balance of evidence on one side or the other. It is easy to admit that in common life high probability is the ground of assent, and that it never can be otherwise: but there is mischief in the use of the same term both for logical inference and for its mixture with matters of guess, or feeling, or unassisted perception. The logician might consent to abandon the word demonstration for popular use, and to adopt another: but it would result that the new word, whatever it might be, would immediately be seized by those who confound what is commonly called argument with what is actually demonstration. Whatever may be the strongest term in use, it will be adopted by strong asserters: nor will he who has shown probable reason, however great, for the adoption of a result of argument, be satisfied unless his conclusion be received as *certain*. What we have here said refers entirely to the use of the word demonstration: the fallacy to be feared is the placing in the result of it, in one sense, the degree of confidence which is only obtained by confounding that sense with another. Two parties, both convinced that a conclusion has a high degree of evidence, dispute whether the evidence *amounts to demonstration*. To settle this point, they sift the evidence most minutely, and perhaps entirely forget to inquire whether they mean the same thing by the word demonstration. Every proposition has its contradiction: and of these one must be true and one false. When the truth of the proposition is proved at once, the demonstration is called *direct*: but when the contradiction is proved to be false, the demonstration is called *indirect*. (ABSURDUM, REDUCTIO AD.)

DEMONSTRATIONS, in military affairs, are operations of any kind which may be performed for the purpose of deceiving the enemy respecting the measures which it is intended to employ against him.

They consist in displaying an apparent activity in forming or repairing a road, or in sending provisions or stores to a particular place, as if preparatory to a march of troops in that direction; in marking out ground as if for an encampment; and in detaching bodies of troops to make false attacks. Such demonstrations are made chiefly with a view of inducing an enemy to divide his forces, and thus weaken his line at points against which the real movement or attack is intended to be directed.

In order to succeed, however, in these demonstrations, they should be made with great precaution, that they may have every appearance of indicating a serious enterprise: even the troops who are to execute them should be unacquainted with the object in view, lest a deficiency of energy should betray the secret to the enemy, who must be supposed to be on his guard against such attempts, and who may consequently take measures to render them useless.

DEMULCENTS are medicinal agents which have the property of protecting sensible surfaces from the action of irritating matter, by hindering it from coming in direct contact with them. They are thus distinguished from diluents, of which water may be taken as an example, which often lessen acrimony by diluting or attenuating the fluid in which it exists. When much water is present in any demulcent liquid, the action is partly that of a diluent, but the chief benefit results from the bland nature of the substance, or from its viscidity. Demulcents are either solutions, such as mucilage of gum arabic, or certain substances mechanically diffused through water or milk, such as wax, spermaceti, or suet. Their beneficial effects are greatest over the mucous surfaces with which they come into immediate contact, such as the throat, stomach, and intestinal canal, but by sympathy their soothing action would appear to be extended to the mucous surfaces of the lungs, and of the urino-genital organs. Mucilaginous substances such as gum, are not easily digested, unless some bitter or astringent principle be taken along with them; so that demulcents pass along the intestinal canal, shielding it from irritating substances throughout its entire length, though less effectually as they proceed, and become mingled with the various secretions in their passage. They thus afford considerable protection to the inner coat of the stomach and intestinal canal against poisonous agents, and for this purpose, milk, gruel, or oil, are frequently employed, though devoid of any power to disarm the substance chemically of its virulence.

DEMURRAGE, the term used in commerce to denote the money payable to the owner of a ship on the part of the shippers or consignees of goods, as compensation for detention beyond the time stipulated for her loading or discharge, as the same is expressed in the charter-party or bills of lading. It is usual to insert in all charter parties the number of working days allowed for the loading of the ship, and also for her unloading, and likewise the sum *per diem* which may be claimed for delay beyond those periods in either case, in addition to the stipulated freight. Sometimes the number of working days for loading and unloading are stated together, so that any delay in the one case may be compensated by greater speed in the other. When the owners of the ship enter her outwards for any port, to receive such goods as may offer, and consequently where no charter-party exists, there is no stipulation for demurrage in the port of loading; but in this case it is common to insert on the face of the bill of lading a statement of the number of days after her arrival at her destined port in which time the goods must be taken from on board the ship, and also the rate of demurrage chargeable daily for any exceeding that time. No claim for demurrage can be set up where a ship is detained by contrary winds or stress of weather, nor where the government interferes to lay an embargo, nor where the port is blockaded by a hostile force, but the claim on the part of the ship ceases so soon as the goods are shipped and the clearances are passed at the Custom-house.

DEMURRER (*demorari*, to stay) is that pleading by which a question of law is raised between the parties to an action at law or suit in equity. The party demurring refuses to proceed farther with the pleadings, and requires the judgment of the court whether the last statement of his opponent is sufficient. A demurrer, therefore, admits the truth of the opponent's allegations, and only questions its sufficiency in point of law.

DENA'RIUS, a Roman coin of silver, so called from containing ten ases. It answered to the Attic drachma. After the first Punic war (about 269 B.C.), the denarius became the representative of sixteen ases, and though Augustus reduced it to twelve, it continued subsequently at the value of sixteen as low as the time of Gallienus. Pinkerton says it was worth eightpence of our money; Hussey estimates its value under the commonwealth at 8½*d.*, under the empire at 7½*d.*, of our money. It was the chief silver coin in Rome for 600 years, down to the time of Constantine I.

The earliest denarii are those which have the helmeted head of Rome, the dioscuri, or the head of Jupiter, upon their obverse. Many of them had chariots, bigæ, or quadrigæ, represented on their reverses; such coins were called *bigati* and *quadrigati*. The half of the denarius was called *quinarius*, as containing five ases; the quarter, *sestertius* as money *semistertius*, containing two ases and a half.

Many of the family Denarii, as those of the Ælian, Æmilian, Calpurnian, Didian, Fulvian, Papinian, Tullian, and numerous other families, were marked on the obverse with the numeral x; others of the same and other family coins have the x crossed by an upright or horizontal bar, sometimes taken for a star or asterisk, but clearly intended to designate the value. The denarii which went for sixteen ases sometimes continued to be marked with x, and sometimes had the numerals XVI. Akerman, in his 'Descriptive Catalogue of rare and unedited Roman Coins,' 8vo, Lond., 1834, vol. i., p. 15–19, has given the actual weight of the silver denarii in Troy grains, from Pompeius Magnus to Constantinus Magnus.

The *denarii æris* or *ærei*, of copper, began with the Emperor Valerian, and were at first washed with silver. Pinkerton thinks they came in the place of the sestertius, and that six of them went to the silver denarius, as six of the later sestertii did.

Roman Denarii.

British Museum. Actual Size. Silver. Weight 60$\frac{6}{10}$ grains.

British Museum. Actual Size. Silver. Weight 58$\frac{5}{10}$ grains.

The word denarius was also applied to the ordinary gold coin of Rome, the *aureus*, in the same manner as the English writers speak of the gold penny of Henry III. *Aurei denarii* are mentioned by Petronius. The denarius aureus was equivalent to 30 silver denarii. The half aureus, in the same manner, was termed quinarius. From the Romans the name was adopted by the Carlovingian kings in France and Germany, and the coin represented the twelfth part of a solidus. The Arabian dinar has also the same origin.

DENEB, an Arabic word, signifying the tail: it generally means the bright star (β) in the tail of the Lion. [LEO.]

DENGUE (*Scarlatina Rheumatica*) is a peculiar febrile disease, conjoined with sudden severe pains in the small joints, which are usually swollen. It is accompanied by heat of skin, intense pain of the head and eyeballs, and the appearance of a cutaneous eruption on the third or fourth day. It is an infectious disease, and has a tendency to develope itself epidemically. The chief peculiarity of this disease is the combination of the symptoms of an exanthematous fever with rheumatic or neuralgic affections of the joints.

This disease has not been observed in Great Britain. "It has been chiefly prevalent in Rangoon, Calcutta, Berhampore, Benares, Chunarghur, in the East Indies; the island of St. Thomas in the West Indies; the Southern States of America; the ports on the Gulf of Mexico; the towns of New Orleans, Savannah, Charlestown, Philadelphia, and New York. It was epidemic in 1824–28, and nothing appears to have been heard of it again till 1849 and 1850, when it again visited the Southern States of America." (Aitken.)

The general course of the disease is, that the patient is attacked with headache, intolerance of light, chilliness, and pains in the back and joints. The small joints swell, the skin becomes hot, the pulse frequent, and the face flushed. The tongue is red. Sometimes an eruption appears at this stage. This state lasts from twelve hours to three or four days, after which it subsides, leaving the patient very feeble. This remission is, however, only temporary. In the course of two or three days there is a return of the fever and pains, with a thickly coated tongue, nausea, and tenderness of the epigastrium. On the sixth or seventh day a scarlet rash appears on the hands, which rapidly spreads over the whole of the body, and gives relief to the febrile irritation. The eruption is very irregular, sometimes being smooth, but at others being papular, vesicular, pustular, or even furunculous. The symptoms gradually subside, leaving the patient with some rheumatic stiffness, and feelings of weakness and mental depression. During the last epidemic at Calcutta the throat was sore, and the articular symptoms were less obvious.

The treatment of this disease consists simply in the palliation of the symptoms. When the nervous irritability and pain are considerable, then opium has been found of essential service. The disease might at first sight be regarded as a mild form of scarlatina. Some of the symptoms, however, are sufficiently characteristic.

DENIER, from the Latin *denarius*, a French coin, originally of silver. It continued in use, through different modifications, as long as the old system of coinage in France lasted; that is, till 1795. Up to that time, accounts were kept in France in livres of 20 sous or 240 deniers: they have been since kept in francs of 10 decimes, or 100 centimes.

Under the kings of the first race the denier weighed twenty-one grains; under the second race, and in the time of Charlemagne, twenty-eight, and sometimes thirty grains; and under Charles the Bald, thirty-two. At the commencement of the third race of French kings the denier weighed twenty-three or twenty-four grains of fine silver. Philip I. began the practice of mixing copper with the silver; and it is in his time that we find the distinction first made between *deniers Tournois* and *deniers Parisis*, the latter being worth a fourth part more than the former. By the time of St. Louis, 1226, the denier had become so debased as to contain not more than six grains and a half of silver; which was probably the occasion of that monarch's issuing a larger class of coins called *gros deniers d'argent*. The term denier was likewise afterwards applied to the gold money of France.

There were formerly current in France several little copper pieces, which having no proper name, were distinguished only by their value in deniers; such were the pieces of 36, 30, 24, 18, 12, 6, 4, and 2 deniers. The pieces of 4 and 2 deniers were coined at Strasburg, for currency in the province of Alsace, pursuant to a declaration of the 6th September, 1695. Those of 6 deniers were coined in the mints of Aix, Montpelier, Rochelle, Bourdeaux, and Nantes, by an edict issued in the month of October, 1709.

The deniers coined toward the end of Louis XIII. were the work of the famous Varin, and are much admired for their execution.

(Le Blanc, *Traité Historique des Monnoyes de France*, 4to, Paris, 1690; Furetière, *Diction. Universel, v. Denier.*)

DENIZEN. Denizen seems originally to have signified a natural-born subject. But now a denizen is an alien-born, who has been constituted an English subject by letters patent of denization, or by the certificate of the secretary of state for the home department (7 & 8 Vict. c. 66). He is in a kind of middle state between an alien and a natural-born subject. He may take lands by purchase, which an alien cannot; but he cannot take by inheritance, for his parent, through whom he must claim being an alien, had no inheritable blood. The issue of a denizen born before denization cannot inherit to him, but the issue born after may. A denizen cannot be a member of the privy council, or sit in either house of parliament, or hold any office of trust, civil or military, or be capable of any grant of lands, &c., from the crown; nor will the British government, it is supposed, consider an alien who has obtained a certificate merely, entitled to British protection, in his own native, or in any foreign country. [ALIEN.]

DENOMINATOR, the number of parts into which a unit is divided in any fraction; thus, in 7-10th's of a unit, 10 is the denominator. [FRACTION.]

DENSITY. This term is absolutely of the same practical meaning as its measure, SPECIFIC GRAVITY, implying that relation of one mass of matter to another, which is suggested by our knowing that a given bulk of the first weighs more than the same of the second. The term has no absolute meaning; gold is more dense than air, but neither is absolutely dense, nor can we assign any meaning to the latter term. It were perhaps to be wished that the shorter term, density, should be employed instead of the longer one, specific gravity; but as custom has referred to the latter term all mathematical considerations connected with the former, we do not here pursue the subject further. [SPECIFIC GRAVITY.]

DENTILS. [COLUMN,]

DENTITION, DISEASES OF. (*Difficult Teething.*) Every infant at the period of birth, is imperfectly organised. There is no structure, and scarcely any tissue of its body, which has attained its due consistence and firmness. Several of the most important organs are entirely rudimentary, and there is not one that is perfect either in structure or function. Development is the great process unceasingly carried on at every point of the system.

Among the organs the first to be developed after birth are the teeth, and the jaws which are to contain the teeth. These organs are agents indispensably necessary to the performance of a primary and essential function—that of nutrition. Before birth there are no teeth, the nutrition of the fœtus being carried on by nutritive matter derived from the mother. For a considerable period after birth there are no teeth, the nutritive matter by which the infant is to be nourished being still formed for it by the mother. But the infant is ultimately to acquire an existence wholly independent of the mother, and from the moment of its birth—nay, long before the period of birth—processes of preparation are going on in its system which have for their object the formation of an apparatus destined to enable it to prepare and digest food independently of its parent. [DENTITION, NAT. HIST. DIV.]

This apparatus, from its most rudimentary state, possesses a highly organised and delicate structure; and it is placed in a position in which its progressive development is attended with peculiar difficulties, which at first view would appear insurmountable. A bony structure has to be formed and to make its way through the dense substance of the gums; at the same time the jaws have to attain a bulk fitted to receive these structures when duly prepared and evolved. The too hasty evolution of the teeth, or the too tardy growth of the jaws, produces evils in the system, by the disturbance of that balance which is indispensable to the orderly and safe progress of all developmental actions.

Supposing the formation of the teeth in the jaws to have proceeded quite naturally up to the time proper for their evolution, at that period they are included in a firm membranous envelope, and are covered by the thick and dense gum. When the process of dentition proceeds in a natural manner, the membrane and the gum are absorbed in order to make way for the passage of the teeth.

This process, even when accomplished in a perfectly natural manner, is almost always attended with some degree of local inflammation. The gum itself is manifestly red and swollen, and is apparently painful and itching, indicated as well by the obvious occasional uneasiness of the infant, as by the constant desire it evinces to press against the gum everything it can lay hold of. The irritation of the gum extends to the salivary apparatus placed in the mouth and its neighbourhood, as is proved by the increased flow of saliva, which is commonly more or less altered in quality, as well as increased in quantity, being thicker and more tenacious than the natural secretion. These symptoms of local irritation are usually accompanied by a slight degree of constitutional disturbance, the skin being commonly hotter and dryer, the face occasionally flushed, the bowels more relaxed, and the infant itself more restless and fretful than natural. The irritation of the gum when restricted within a moderate limit seems to be the necessary consequence of the developmental process that is going on. The effect of the local irritation, namely, a determination of blood to the salivary apparatus, occasioning an increased flow of saliva, and that of the constitutional disturbance, namely, a determination of blood to the mucous membrane of the intestines, occasioning diarrhœa,—appear to be remedial rather than morbid, to be evacuations established by nature for the purpose of relieving over-distended vessels and over-excited nerves.

When the infant is in a state of sound health, and when the process of dentition proceeds in a natural manner, the local and constitutional evils attending the evolution of teeth amount to no more than have now been described; but when the infant is in a state of either congenital or acquired disease, or when the natural course of the process of dentition is disturbed, evils result always serious and often fatal.

Suppose that the formative proceeds faster than the absorbing process; that the teeth grow with a rapidity with which the action of the absorbents is not commensurate, the necessary consequences are, that the tooth is forced against the gum, that the investing membrane is compressed between them, and that this pressure is communicated to the delicate and soft pulp on which the organisation of the tooth is still proceeding. The effects of the irritation thence induced will vary according to the degree of pressure, the sensibility, and irritability of the individual, and the pre-disposition of its natural or acquired constitution to disease. In some it may produce only a slight aggravation of the local and constitutional ailments already described; in others it may produce every form of disease to which infancy is subject, attended with every symptom appertaining to such diseases.

In the infant, the mucous membrane which lines the alimentary canal, from its commencement in the mouth to its very termination, is highly sensitive and irritable; the membrane which covers the external surface of the body, the skin, which possesses essentially the same structure as the internal lining membrane, and between which there is the most intimate sympathy, is alike sensitive and irritable; the mucous membrane which lines the air-passages, and which forms the air-vesicles of the lungs, is scarcely less sensitive and irritable. Morbid irritation excited in any of these extended and most important surfaces is readily propagated to the great nervous centres, the spinal cord and brain, in which are induced, often with extreme rapidity, some of the most formidable diseases to which the human body is subject; and from diseases established in the spinal cord and brain disease is reflected back upon the muscles. Thus the most prominent diseases produced by abnormal (irregular) dentition have their seat in the stomach, the intestines, and all the organs which form a part of the digestive apparatus; in the external skin, in the air-passages and lungs, in the spinal cord and brain, and in the muscles of voluntary motion.

The irritation attendant on abnormal dentition commences in a portion of the mucous surface of the digestive apparatus, and from its source in the mouth it is readily propagated to the stomach, intestines, and liver, producing in the stomach pain, nausea, vomiting, flatulence, acid eructations, &c.; in the intestines, griping pain, flatulence, diarrhœa; in the liver, disordered secretion of bile, in consequence of which the fæcal evacuations are greatly altered in quantity and quality, being at one time too scanty, and at another time too copious, sometimes light or clay-coloured, and at other times dark-green, spinach-like, and preternaturally fœtid, mixed with large quantities of unhealthy viscid mucus.

The external skin sympathising with the irritation set up in the internal mucous surface, is constantly affected with eruptions of various names and natures, sometimes attacking the scalp, sometimes surrounding the lips and extending over the face, and at other times covering the whole body.

The irritation is propagated from the mucous membrane of the mouth and fauces to that of the air-passages and air-vesicles, inducing hurried, difficult, and painful respiration, frequent cough, and all the symptoms of inflammation of the lungs.

There is the closest possible connection between the skin, the digestive surface, the respiratory surface, and the great nervous centres, the spinal cord and brain. Any irritation excited in the former is readily propagated to the latter. There is a direct route by which the intercourse is established. The nerves proceeding from all these surfaces take a direct course to the spinal cord and brain, where they communicate the irritation which they receive, and excite, among other diseases, more especially that which constitutes hydrocephalus acutus, or water in the head. This disease, among the most formidable to which infancy is subject, and the most common cause of which is abnormal dentition, is preceded by the start in sleep, the slight chill, hardly amounting to rigor; the flushed face; the sudden, darting, transient pain in the head; the unusual drowsiness; and then come the sudden start from that deep sleep, with a loud scream; the injected eye, the dilated pupil, followed by the constant rolling of the head upon the pillow, the loss of sight, and the progressively increasing insensibility and coma. The irritation thus produced in the spinal cord and brain is quickly reflected back upon those muscles the action of which depends upon an influence derived from these great nervous centres—the muscles of volition, which are affected with twitchings, spasms, convulsions, sometimes passing into chorea, epilepsy, catalepsy, and tetanus.

When the acute symptoms induced by inflammation of the brain, followed by effusion, pass away without immediately destroying life, it is often only to leave a state of permanent idiotcy far worse than death.

Besides all these evils produced by abnormal dentition, there is one specific disease that results from it of a most formidable nature, and often fatal. This affection may be termed the disease of development; it is commonly called infantile remittent fever. The accession of this disease is denoted by languor, lassitude, chilliness, shivering, succeeded by heat of skin, perspiration, and accelerated pulse. The little patient is spiritless, discontented, and fretful. Yawning, sighing, marked increase of irritability, unusual mutability of temper, loss of appetite, perhaps alternating with importunate desire for food, which when given often cannot be eaten, some peculiarity of respiration, and at last impatience of light and sound, accompany or quickly follow a distinct febrile attack. The feverish symptoms disappear or remit soon to recur or exacerbate; and these remissions and exacerbations are characteristic marks of the disease. The colour of health is gone, and the colour often changes. A flush of the countenance, preceding slight rigor and paleness of face, is succeeded by slight headache. There is a remarkable desire to pick, principally the nose, sometimes the lips and fingers, often other objects; frequently the breath is offensive, and cough, headache, and griping pains in the bowels are present, with more or less of sickness, faintness, sighing, starting, more particularly in sleep, moaning in sleep, grating the teeth, sleeping with the eyes half open, and a relaxed or on the contrary an exceedingly constipated state of the bowels. Occasionally the pupils suddenly dilate, perhaps only one pupil, and then as suddenly contract. "Perspiration is part of fever, and this is sometimes observed night after night succeeding to no very remarkable heat of skin, but to a great drowsiness, which in itself is a proof of exacerbation, though the accelerated pulse of fever may be wanting. The moaning, picking, or starting, with any of these conditions, constitutes part and parcel of this disorder. Sometimes the ailment is slight in degree, or it may assume an acute form with all the fire and anger of a hot fever. Sometimes it is typhoid in its type. Whatever character may be assumed by this disorder, it is coincident with an irregular course of the development of some organ of the body; and commonly the irregular development is in the nutrient organs, and of these most commonly the teeth and jaws."

Fatal disease may arise from abnormal dentition long before the usual period of cutting the teeth. A turgid condition of the vessels about the soft and delicate pulp, and in the membrane that envelopes the whole rudimentary tooth, may compress the dental and even the maxillary nerves; and pressure on these nervous tendrils may, under certain conditions, be tantamount to pressure applied directly to certain parts of the brain; hence irregularity in the course of growth, at the earlier period of teething, may produce a sufficient degree of pressure to excite a high degree of irritation in the brain, producing even fatal convulsions. Many striking cases of this kind are on record, of which the following brief history may serve as an example: A fine healthy-looking child, of a strong healthy mother, died, at thirteen weeks of age, of a convulsive fit. The cause of death was ascertained, at the earnest wish of the mother, by a careful examination of the body after death. The internal organs, for the most part, were healthy; the stomach contained only a little milk; the mucous surfaces of the intestines were free from disease; the contents of the thorax were healthy. In the head, the membranes that envelope the brain, and more especially the pia mater, were more tinged with blood than natural, but the brain itself was healthy. The jaws were carefully examined. "The capsules of the incisor teeth were large and very vascular, much more advanced than usual. With a lancet, the cartilaginous rim of the lower jaw was attempted to be removed, with a view of exposing the capsules of the molar teeth; but these were so unusually distended with fluid, that the instrument cut into them and let it out. This was an example of development proceeding too hastily."

It is common for the symptoms of irritation which attend on the evolution of the teeth to appear about the third or fourth month; they usually precede the appearance of the teeth by several weeks, and they occasionally subside and then re-appear a short time before the tooth makes its way through the gum.

Disease arising from abnormal dentition is not confined to the period of infancy. In children of irritable constitutions in whom the maxillæ are imperfectly developed, the irruption of the second or permanent teeth is sometimes attended with serious and even fatal disorders. Nay, even the period of adolescence is by no means free from severe diseases produced by this same cause; for in consequence of the development of some of the teeth having been preternaturally delayed, or in consequence of an imperfect development of the jaws, at the period when the dentes sapientiæ are about to appear, delicate, nervous, and irritable subjects are not unfrequently affected with swelling of the parotid and submaxillary glands, painful and sometimes periodical affections of the ear and face, slight or recurring ophthalmia, irregular convulsions, epilepsy, and chorea; which affections have disappeared at once upon the irruption of the teeth or the removal of the local irritation.

Animals are not afflicted with these or any analogous evils from the evolution of their teeth, and they are produced in the human species altogether by the unnatural circumstances in which the infant is placed in the present artificial state of society. The chief causes of these grievous evils are: 1. Food, unnatural in quality and too great in quantity. It is seldom that an infant lives solely upon its natural food (human milk) during the early months of its existence. If it take other food, that food is either digested or it is not. If it be not digested, numerous ailments are produced; if it be digested, the system is too highly nourished, and becomes too full of blood, from which it is easy to see that any one or any number of the diseases which have been described may result. 2. The practice, too common in this country, of keeping the heads of infants and young children very warm by clothing, by their wearing flannel caps, and by having their heads almost constantly wrapped in a warm woollen shawl, from the dread of their catching cold. The naturally great determination of blood to the head is too much favoured by this practice, which co-operates more powerfully than may at first view be apparent with the other circumstances that conspire to produce disordered dentition. 3. The confinement of infants in close and heated apartments, in the impure air of large towns and cities without exercise. Such children in whom all the evils of dentition are most frequently produced in the severest forms, are deprived of the natural stimulus afforded to the varied processes of growth by pure air and active exercise.

The treatment of the various and formidable diseases produced by abnormal dentition can never be judiciously conducted without a constant reference to the causes on which they depend. Without a proper regulation of the diet, clothing, air, exercise, and a state of the bowels, nothing can be effectually done to prevent the occurrence of the most formidable of these evils. When they are actually present no remedy can be other than palliative which does not aim at two things: first, the entire correction of everything ascertained to be faulty in the diet, clothing, &c. &c.; secondly, the removal of pressure upon the nerves, produced by the advancing and unliberated tooth, which occasions all the mischief. "As soon therefore as any of the affections now described, or any others which can possibly be supposed to arise from this cause, make their appearance, the gums should be carefully examined, and wherever there is any unusual redness or turgescence, and especially if it occur over the part where the next tooth is expected to appear, the including parts should be freely and effectually divided. It is not sufficient that the incision should merely pass through the gum, the lancet must be carried down to the rising tooth itself, and only stopped when the resistance of its point is felt against the edge of the instrument. The form of the gum-lancet should be broad and somewhat rounded, and its edge extremely sharp. The only precaution necessary in its use is so to direct it in making the incision that the cord of connection between the temporary and permanent tooth shall be carefully avoided, which is readily insured by directing the edge rather towards the outer part of the gum.

"The prejudices of former times against this simple and most efficacious operation are fast yielding to the frequent evidence of its harmlessness and utility. It is impossible for the most prejudiced to witness the effects which continually result from it without becoming a convert to its use. In the midst of the most imminent danger, when death has almost been anticipated as the only relief from severe and hopeless suffering, this simple and trifling operation has, in innumerable instances, restored the little sufferers to their parents in a state of ease and safety, and in so short a space of time as would scarcely have appeared credible."

There are few cases in the management of disease which require more prompt decision in the application of remedies or more judicious selection of remedial agents than some of the sympathetic affections which have been now adverted to. Life will often depend on the choice of the remedy which is made, and the cautious boldness with which it is administered. It is not possible here to pursue the discussion of this subject further than merely to add that the bowels should be constantly kept in a somewhat loose state; that if a slight degree of diarrhœa be naturally established, nothing whatever should be done to check it; that even when the purging becomes considerable, it should be only moderated, not stopped; and that the most extreme caution should be exercised in meddling with any eruptions upon the skin.

DENUNCIATION. [DILIGENCE.]

DEODAND (*Deo dandum*, given to God). This name was given to whatever personal chattel occasioned the death of a man without the default of another, and also to the instrument with which murder was committed; because by our ancient law these chattels were forfeited to the crown, to be applied to pious uses and distributed in alms by the high almoner.

Blackstone supposes "that the custom was originally designed in the blind days of popery as an expiation for the souls of such as were snatched away by sudden death, and for that purpose ought properly to have been given to holy church, in the same manner as the apparel of a stranger who was found dead was applied to purchase masses for his soul." But it is perhaps more reasonable to imagine that it was a civil institution intended to produce care and caution on the part of the owners of cattle and goods, and that the subsequent application of the things forfeited has been mistaken for the origin of the law itself. The custom was also a part of the Mosaic Law. (Exod. xxi. 28.) In England it prevailed from the earliest period, the custom being mentioned by Bracton, one of the earliest writers on English law, who lived in the reign of Henry III. "Omnia quæ movent ad mortem sunt deodanda," which is Englished in the 'Termes de la Ley:'—

> What moves to death, or kill'd the dead,
> Is deodand, and forfeited.

Deodands were abolished by stat. 9 & 10 Vict., c. 62. (Blackst. 'Comm.,' Mr. Kerr's ed., vol. i. p. 297.)

DEPARTMENT (or in French DEPARTEMENT), a territorial division of France, introduced by the States General in the latter part of the reign of Louis XVI. The departments are divided into arrondissements, cantons, and communes. They will be found described under France, and each department by name, in the Geog. Div.

DEPARTURE, a nautical term used to indicate the number of miles which a ship has sailed eastward or westward; and it always has reference to a certain meridian which the ship was upon, when her previous position had been calculated.

When a ship sails on any course but true north or south, she leaves or "departs" from her meridian: hence the word.

From the obliquity of the course in such cases, when not sailing due east or west, a triangle is formed, of which in "dead reckoning" the base is assumed to be the "departure," the perpendicular being the difference of latitude, and the hypothenuse the distance. In its most simple form, that of plane sailing, the earth's surface is for convenience supposed to be flat; hence the term departure can only be applicable to short distances, such as a day's run.

The difference between departure and longitude may be thus illustrated: If we construct a right-angled triangle, of which the base contains the number of given miles of declination, and make the acute angle at the base equal to the given latitude, the hypothenuse will measure the corresponding geographical miles of longitude,—or, by logarithms, Cos. Lat. : Dep. : : Rad. : Diff. Long.

$$\therefore \text{ Diff. Long} = \frac{\text{Dep.} \times \text{Rad.}}{\text{Cos. Lat.}} \text{ and}$$

$$\therefore \text{ Dep.} = \frac{\text{Cos. Lat.} \times \text{Diff. Long.}}{\text{Radius.}}$$

Taking a departure is the ascertaining of the ship's position with regard to some prominent headland which is in sight at the time of commencing what is called a sea log, and it fixes the starting-point for the voyage. This is generally done by one of three methods, namely:—

1. Either a single bearing [Bearing] is taken of some known object on shore, and its distance *estimated*; or,

2. A bearing is first taken of one object, and after sailing a measured distance on a known compass course, a second bearing is taken of the same object, and the required side of a triangle thus found is measured or computed; or,

3. Two land objects being in sight, the bearing of each is taken at the same moment in the ship, and from these bearings laid off as reversed upon the chart the exact distance is at once measured: that between the two objects on the chart forming the base line of the triangle.

In estimating at sea distances from high land in sight, so much depends on the state of the atmosphere [Refraction] that even a practised eye is liable to considerable error; so that a second or cross bearing, if obtainable, is always to be preferred.

The position of a ship from the land on taking a departure, is usually considered as if the first course in the traverse. [Sailings; Navigation; Longitude.]

DEPARTURE. [Pleading.]

DEPHLOGISTICATED. A term used by the chemists of the last century to denote bodies which had been burnt; or, according to the then prevailing theory, deprived of their phlogiston. [Chemistry, *George Earnest Stahl.*]

DEPHLOGISTICATED MARINE ACID. [Chlorine.]

DEPLOY, to extend in a line of small depth, an army, a division, or a battalion, which has been previously formed in one or more columns.

DEPORTATION. [Banishment.]

DEPOSIT. This term is applied to the sum of money which, under 43 Geo. III. c. 46, a man may deposit with the sheriff after he is arrested, instead of putting in special bail. [Arrest.]

Deposit is also used for any sum of money which a man puts in the hands of another as a kind of security for the fulfilment of some agreement, or as a part payment in advance.

The Roman word *depositum* signified anything which a man put in the hands of another to keep till it was asked back, without anything being given to the depositarius for his trouble. The depositor was called deponens or depositor. The depositary was bound to take care of the thing, and to make good any damage that happened to it through fraudulent design (*dolus*) or gross neglect (*lata culpa*). The depositor could recover the thing by action; but the depositary was entitled to satisfaction for any loss that he sustained in the matter of the deposit by any default (*culpa*) on the part of the depositor. The depositary could make no use of the deposit, except with the permission of the depositor, either given in express words or arising from implication. If a man refused to return a deposit, and was condemned in an action of deposit (*actio depositi*), infamy (*infamia*) was a consequence of the condemnation.

('Dig.' 16, tit. 3; Juvenal, 'Sat.' xiii. 60.)

DEPOSITION in its extended sense means the act of giving public testimony, but as applicable to English law the word is used to signify the testimony of a witness in a judicial proceeding reduced to writing. Informations upon oath and the evidence of witnesses before magistrates and coroners are reduced into writing in the very words used by the witnesses, or as near as possible thereto. Evidence in the Court of Chancery is now, under 15 & 16 Vict., c. 86, taken orally by examiners who write down the evidence given in the form of a narrative, which is read over to and signed by the witness. According to the ancient practice, which may in some cases be still resorted to, evidence was taken in written answers to interrogatories, which were in writing, either by commissioners appointed by the court for that purpose in the particular cause, if the witness resided at a greater distance from London than 20 miles, or before the examiners of the Court of Chancery. The Court of Chancery has power to grant a commission for the examination of witnesses residing abroad; and by the 1 Will. IV., c. 22, extending the provisions of the 13 Geo. III., c. 63, the courts of law at Westminster, in actions pending before them, have power to order the examination of witnesses residing in any of her Majesty's foreign dominions. When a witness is above the age of seventy, or very infirm, or about to go abroad, so that his testimony may be lost before the regular period for his examination arrives, the Court of Chancery will order him to be examined *de bene esse*, as it is termed; that is, his examination is received for the present, and will be accepted as evidence when the proper time for taking the other evidence in the cause arrives, if the witness cannot be then produced. Courts of law do not possess similar power without the consent of both parties, but in order to enforce consent they will put off the trial at the instance of a defendant, if the plaintiff will not consent: and if the defendant refuse, will not give him judgment in case of nonsuit.

The Court of Chancery will also, upon bill filed by a person in the actual and undisturbed possession of property, and who has therefore no means of making his title the subject of judicial investigation, but which nevertheless may be materially affected by the evidence of living witnesses, allow the witnesses to be examined in *perpetuam rei memoriam*, that is, to perpetuate testimony. This is done in order that if any of the witnesses should die before the title to the property is disputed, their evidence may be preserved, otherwise a claimant might lie by until all the evidence against him was lost.

Depositions are not admitted as evidence in courts of law, unless the witness is either dead, or, from some cause, beyond the control of the party seeking to read the deposition, cannot be produced, or against any other persons than the parties to the proceeding in which they were taken, or claimants under them, and who had the opportunity of cross-examining the witness. In cases, however, relating to a custom, prescription, or pedigree, where mere reputation would be good evidence, a deposition may be received as against a stranger.

Depositions taken in Chancery *de bene esse* before answer put in, unless the defendant is in contempt for refusing to answer, are not admissible as evidence in a court of law, because until the defendant has answered he could not have an opportunity of cross-examining the witness; but the Court of Chancery will sometimes direct such depositions to be read. Such order, however, while it concludes the parties, is not binding upon the court of law: of course, however, if the depositions be not read and the decision should be contrary to justice, the Court of Chancery would interfere as between the parties. [Equity; Evidence.]

DEPRESSION (Algebra), the reduction of an equation to a lower degree, by dividing both sides of it by a common factor. Thus $x^3-x-6=0$ having been found to have 2 as one of its roots is *depressed* to an equation of the second degree by dividing by $x-2$, which gives $x^2+2x+3=0$: that is, the two roots of the latter equation are the two remaining roots of the former.

DEPRESSION, ANGLE OF, is the angle by which a line drawn from the eye to any object dips below the horizon. [Elevation, Angle of.]

DEPRESSION OF MERCURY. [Barometer.]

DERIVATION. The term *law of derivation* almost explains itself. Thus in finding the successive differential co-efficients of a power of x, the law is,—to get the next differential co-efficient, multiply the last by its exponent, and reduce the exponent by a unit. To treat of derivation in the most general sense would be to write a work on mathematical analysis, of which it may be said that most of its difficulties arise from want of sufficient knowledge of methods of derivation. But there is a more restricted use of the term, derived from the work of Arbogast, in which it applies to those laws of derivation which spring out of Taylor's Theorem. Hence the differential calculus, considered either in the manner of Lagrange, or in that of Arbogast, is sometimes called the calculus of derivations. Lagrange himself calls the differential co-efficient a derived function, the objection to which is the application of a generic term to one of its particular cases. For the successive logarithms, sines, &c., differences, integrals, &c., of a given function, are also functions derived from the original in different ways. Nevertheless, the fundamental processes of the differential calculus have appropriated the word *derivation*; but in this way: the *derived function* nearly always means the differential coefficient, while the substantive *derivation* is nearly always used in reference to the method of Arbogast.

DERVISH is a Persian word, properly an adjective, which signifies poor, indigent; as a substantive it is used to denote a religious mendicant, hermit, or any one who retires from social life in order to devote himself entirely to religious contemplation. It is synonymous with the Arabic *Fakir*, and both expressions are chiefly employed to designate a class of persons in Mohammedan countries nearly corresponding to the different orders of monks among the Christians. It would be difficult to determine the age to which the origin of the dervishes is to be referred. From time almost immemorial, pious men in the East, as elsewhere, seem to have thought it meritorious to renounce the enjoyment of temporal things and the ties of domestic and social relations, and to live in poverty and solitude for the purpose of turning their thoughts altogether towards spiritual matters. Oriental tradition makes the order of hermits as ancient not only as St. John the Baptist or Elias, but even as the time of Seth. In the *Koran* poverty is recommended as meritorious; and Mohammed is reported to have said, "See that ye come poor before God, for the poor shall have the first place in his mansion." Jâmi, the well-known Persian poet, is the author of an esteemed work on the lives of the *Sûfîs*, or Mohammedan mystics. Among the Turks several orders of fakirs or dervishes exist. The principal one is that of the *Maulavis*, founded by the celebrated Persian poet Jelâleddin Rûmi, who died in 1262. The dervishes of this order have a great monastery at Galata, and another at Iconium. Their demeanour is very humble, and their robes are extremely coarse; besides the fast during the month of Ramazan, they keep a weekly fast on every Thursday. It is part of their religious practices to turn round with great velocity to the sound of a pipe, repeating loudly and slowly the words "La illah illahlah," dwelling on each syllable; and, when the music ceases, to stop at once, without showing symptoms of giddiness. They may leave their order, and are then released from their vow of chastity, and permitted to marry. Some amuse the common people by tricks of legerdemain, or apply themselves to the practice of sorcery and conjurations. They are notorious for their fondness for intoxicating liquors and for opium. They have convents in nearly all Mohammedan countries, which serve the travelling pilgrims of this order as inns. The order of the Rufâis, or howling dervishes, founded 1182, by Sheikh Ahmed Rufâi, is distinguished by the strange excesses of self-mortification to which its members are carried by their fanaticism. In their weekly assemblies in the hall of their convents, some are always selected to hold a red-hot piece of iron between their teeth till it becomes cool, while the others make deep incisions in their bodies with sharp-edged instruments. Another class of dervishes is that of the *Calenders*. They are distinguished by the singularity of their dress, which is sometimes made of party-coloured cloth, and sometimes consists of a tiger's or sheep's hide, or is made of iron. Frequently the Calenders go about half-naked, with their skin painted red or black. They wear feathers in their ears, and have their heads covered with hats or turbans of a fanciful shape. In their girdles they carry a plate or bowl, which they hold out to receive charities. They often visit coffee-houses and other places of public resort to preach, and act as if they were inspired. In their religious opinions, the greatest variety prevails. There are other orders, distinguished by certain peculiarities, some of which are of older origin than the above, but none are of equal importance. The dervishes do not seem to be much respected by the public; they are considered as hypocrites, who have assumed a sanctimonious appearance in order to have a pretext for idleness, and who clandestinely indulge in the grossest licentiousness. All dervishes, with the exception of the Maulavi, are allowed to marry; but they are obliged to sleep one or two nights in the convent of their order.

(Paul Rycaut, *The Present State of the Ottoman Empire*, 1668; Von Hammer, *Geschichte der Osmanischen Reichs.*)

DESCANT, in Music (the etymology is doubtful) signifies, in strict language, a melody or air, extemporised on a *canto-fermo* [Plain Chant], or, in other words, an enlarging *all'improvviso*, that is, unpremeditatedly, on a given subject, which subject, sung by another voice, or other voices, forms the accompaniment of the descant. Thus the term was understood in the 11th and 12th centuries, both by Franchinus and John de Muris; but afterwards it became synonymous with counterpoint. [Counterpoint.] It has now, however, fallen into disuse, and is seldom met with, except in dictionaries.

DESCENT, in English law (from *discent*, Norman French and so written in our older law books), may be defined the act of law by which on the death of the owner of an inheritance, without making any disposition thereof, it is cast upon another as an heir. Inheritance is sometimes used in the same sense, though it rather signifies that which is, or may be, inherited, or taken by descent. (Littleton, sect. 9.)

1. The law of inheritance with respect to descents which have taken place since, or shall take place after the 1st of January, 1834, is now regulated by the Act 3 & 4 Wm. IV. c. 106, but some notice of what the law was before that time is necessary; since it is the constant practice, in the investigation of titles to property, to inquire what happened fifty or sixty years ago.

2. The death of the owner of the inheritance is the occasion of the descent of it. In his lifetime, there can be no descent, and therefore no heir, though there may be an "heir apparent," or "heir presumptive;" an heir apparent being he who must be the heir, if he lives till the inheritance descends; an heir presumptive, he who may be forestalled by the birth of a nearer heir.

3. The person who dies must be at his death owner of the inheritance, or no descent of it will then take place.

4. Inheritances, *hereditaments*, things which may be *inherited* or *taken by descent*, are various. The principal of these is the crown, the descent of which differs in one material respect from that of a private inheritance, inasmuch as where there are no sons of the king, an elder daughter takes the whole of the inheritance, in exclusion of the younger sisters. Again, dignities and honours, as baronies and other peerages, are descendible, according to the limitations contained in the patents by which they were created. If created by summons in the first instance, they are called dignities in fee, and are descendible to females. [Barony.] Finally, all the subjects of real property and all annuities, offices, and whatever other things may be "held in fee," are "descendible," and this whether they are in possession, reversion, remainder, or expectancy. So are all rights and titles to things that may be held in fee, and the expectancy of an heir apparent or presumptive. There are also "descendible freeholds," that is, estates created by leases for lives, which, though not estates in fee, may during their continuance be inherited as if they were. It has been already noticed [Chattel] that the large class of things called chattels are not generally the subject of descent, but that some of them are.

5. Upon the death of the owner, the law casts the inheritance upon the heir, without any act done by him, or price paid for his acquisition: in both these respects, the present law of descent differs from the old feudal customs from which it is derived. According to the old feudal customs, upon the death of the tenant of a fee, the lord of whom it was held was entitled to take and retain it till the heir, for whom proclamation was made, appeared, and paid a sum of money called a relief [Relief] as the consideration for his admission into the tenancy; whereupon "seisin" or possession was given him, and he took the "oath of fealty" [Fealty], and if the tenancy was by "knight's service," "did homage" [Homage] also to the lord. All this was more like a new donation, than the present quiet succession of an heir. The descent of copyholds, however, is still regulated much in the manner described. The heir was not however formerly, to the same extent as now, subject to the charges and debts of the deceased tenant, in respect of the property descended [Assets]; and he had also an advantage, which is much insisted and commented upon by the old law writers, though its value is not so apparent to us. The descent of an inheritance of which the rightful owner had been *disseised* or unlawfully dispossessed, prevented him from making an *entry* upon the heir of the disseisor, or bringing an action of ejectment, the right to maintain which is founded upon the right to make an actual entry, and left him only "a writ of right," or other real action, for the recovery of his property. One whole chapter of Littleton's 'Tenures' is taken up with treating of descents which "toll" (take away) entries, but a late Act (3 & 4 Wm. IV. c. 27) prevents descents from having any longer this effect. The present law of descents qualifies materially in one respect the title of the heir to the inheritance descended. Though it makes him as completely the owner of it as if he had purchased it, as to right of enjoyment and power of alienation, it does not allow it at his death to descend as if he had purchased it; but, on the contrary, declares that it shall descend as if he had never had it. Such at least is the new law (s. 1, 2 of the Act). The heir of an inheritance must be always the heir of the last "purchaser" of it, that is, of the last person who acquired the property "otherwise than by descent, or than by an escheat partition or inclosure, by the effect of which the land shall have become part of, or descendible, in the same manner as other land acquired by descent." The practical importance of this rule cannot be understood without knowing who the person is who in any case is designated by the law as the "heir" to another.

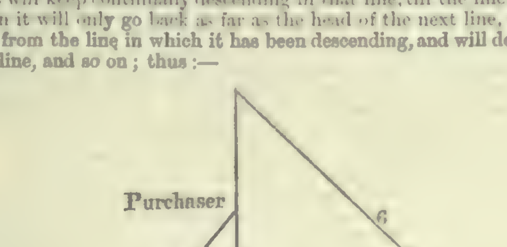
As to descents in fee simple, the fundamental rule is, that any person *of kin* to another, that is, descended from the same ancestor, however distant, may be his heir, but that no person connected with him by marriage or affinity only [Affinity], can inherit to him. If the son inherits to the father, his mother cannot succeed to him, for though she may be heir to the son, she cannot be heir to the father, from whom, and not from the son, "the descent is to be traced." On the other hand, if the father inherits to the son, the mother may succeed to him, for though she cannot be the heir of the father, she may be the heir of the son. The fee, fief, or feud, which may thus now descend to the kindred of the purchaser *in infinitum*, was once nothing more than a life interest given to the tenant or holder of it in consideration of the military services to be rendered by the latter to the donor. [Allodium.] The fee was afterwards permitted to descend to the issue of the original grantee, and in process of time to his *collateral* heirs. This was only effected by means of a fiction; for so firmly settled was the notion that "the blood" (descending) alone of the purchaser or original grantee could be allowed to inherit, that the feudal law was never brought to allow collateral heirs, as such, to be heirs. But when a feud was granted *ut antiquum*, that is, to be held by the donee as if it had descended to him from some remote unknown ancestor, then the law permitted collateral relations however distant, that is, relations descended from any common ancestor, however remote, to inherit. For it was not known how far distant the ancestor was who was supposed to have been the purchaser, nor who he was, and it was sufficient that the heir *might* be a descendant of his. (See for the early history of inheritable fiefs, Robertson's 'Charles V.' Sullivan's 'Lectures;' Wright's 'Tenures;' Gilbert 'on Tenures,' by Watkins; Butler's 'Coke upon Littleton,' 191, a, n. where there is an excellent comparison of the Roman and feudal laws of inheritance.)

While the law however went thus far, it did not, for reasons which some writers have attempted to explain, allow the *lineal ancestors* of the purchaser of the *quasi* ancient feud to inherit it, nor his relations by the half-blood, that is, persons descended not from the same father *and* mother as the purchaser, or any lineal ancestor of his, but from one of them only. Still further exclusions followed from the rule which was afterwards established, that the heir of the fee must be the heir of the person last *seised* or possessed of it, as well as a kinsman of the whole blood to the actual purchaser. Among the practical consequences of this rule were the following: That if the child of the actual purchaser inherited to him, and became seised, the purchaser's child by another wife could not succeed, because only half brother to the person last seised; and that if the father's brother inherited to the son and became seised, the mother's brother could not succeed, because only related by marriage to the person last seised. All these exclusions and the fictions of the ancient feuds are done away with by the new Act, the effect of which is, as before said, to admit among the heirs of the purchaser all his kindred, both of the whole and the half blood, and notwithstanding any previous descent to any heir of his. This it does by enacting that every lineal ancestor shall be capable of being heir to any of his issue (s. 6); that any person related to the purchaser by the half blood shall be capable of being his heir (s. 9), and that in every case descent shall be traced from the purchaser (s. 2). Still, however, the wife or her relations cannot inherit to the husband, nor the husband or his relations to the wife. But the hardship of these exclusions is at least mitigated by the law of dower and curtesy, which must be read together with the law of descent as one law. It remains to show in what order the kindred of the purchaser inherit. The old law on this subject is reduced by Blackstone to seven rules, which have been generally copied by later writers; but the new Act so interferes with them, and they seem, besides, to be so capable of being simplified, that we shall propose instead of them the following rules, which, it is believed, embody the present law on this subject. We shall follow Blackstone's plan of stating the rules in the order in which they may have to be applied in searching for an heir.

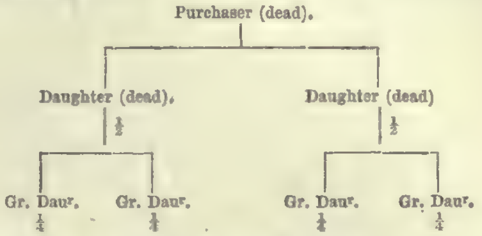
1. The child (if any) of the last owner deceased is the heir of the purchaser. Thus not only is the child of the purchaser his heir upon his death, but if any other heir of the purchaser dies after having inherited, *his* child is the heir of the purchaser.

2. The person through whom another must trace his descent from the purchaser is (if living) the heir before that other person. Now, bearing in mind that descent is always to be traced lineally, that is, either from parent to child, grandchild, &c., or *vice versâ*, it follows that the purchaser's child must, if living, inherit before *his* child, the brother before the nephew, the father before the brother or the grandfather, &c. If the purchaser had a child who died in his lifetime, leaving a child, that child is the purchaser's heir, according to rule 1; for the expectancy of the child of being next heir to the purchaser descended upon his death to his child, as being his next heir, who consequently becomes, upon the purchaser's death, *his* heir. It is surprising that this plain and certainly true explanation of the effect in question has been overlooked by all the writers on the law of descents, who lay down a separate rule (the 4th of Blackstone's) to account for it.

According to these rules 1 and 2, the effect of which is very much to simplify the course of descents, when an inheritance has once got into a *line*, it will keep continually descending in that line, till the line ends; and then it will only go back as far as the head of the next line, which springs from the line in which it has been descending, and will descend in that line, and so on; thus:—



3. Of persons related to each other, as brothers and sisters, the males inherit before the females: the former successively in order of birth; the latter altogether in equal shares, being therefore called *coparceners*. (This rule is qualified by rule 5.) Hence the sons of the purchaser inherit before the daughters, and first his eldest son, then his second, &c.; then all his daughters together. It makes no difference whether the coparceners are related to each other by the whole or the half blood. This division among females often causes the minute splitting of inheritances, as thus:—



According to the custom of *gavelkind*, all the sons, and in default of sons, all the daughters inherit together as coparceners. As to the custom of Borough English, see that title.

4. Every male ancestor inherits before any female one. This is qualified by rule 2. (See s. 7 of the new Act.) Hence the father takes before the mother, &c., but not the mother's father before her, for he claims through her.

5. Those who are relations by the half blood to the purchaser inherit next after their brothers and sisters, who are relations by the whole blood to the purchaser. (Qualified by rule 4 and 2: see s. 9 of the new Act.) What the half blood is has been already explained. Thus (by an exception to rule 3) the half brother takes after the whole sister, and the half sister does not share with the whole sister. The like is true of half uncles, &c. According to this rule 5, however, the purchaser's brother of the half blood on the part of the *mother* does not take next after his brother of the whole blood, for such half brother claims through, and therefore takes *after* (rule 2) the mother, who (rule 4) is postponed to the father.

6. The mother of the more remote male ancestor inherits before the mother of the less remote; and the mother of any male ancestor before the mother. (See s. 8 of the new Act.) Thus the father's mother takes before the mother, and the father's father's mother before the father's mother, &c.

These six rules, read one with another, will, it is believed, point in any case to the heir. It is observable, and in this respect the new differs from the old law, that there cannot be a nearer heir born after the heir who has inherited. Formerly the sister of the purchaser might inherit, and a brother of his be afterwards born, in which case the inheritance *shifted* to the latter. But at present this cannot be, as the father takes before his children (rule 2), and all children in the womb are considered by law as if born. The practical difficulty in finding an heir or proving a title by descent is, not to understand the law, but to ascertain and prove the facts on which the law must operate. (As to this, see Burton's 'Compendium of the Law of Real Property.') The new Act provides against the difficulty of tracing descent from the purchaser, by the enactment that the last owner shall be always presumed to be the purchaser till the contrary is proved (s. 2).

To comment at length upon the rules regulating the course of descent is beyond our limits. Some observations and references are however necessary. Rule 3, which makes the eldest son, brother, &c., sole heir, exclusive of the other children, or the other nephews and nieces, &c., is well known by the name of "the law of primogeniture." It is almost peculiar to our country, not having been observed by the ancients, and being generally abolished where it existed on the Continent and in the United States of America. For the history of this rule, see Hale's 'History of the Common Law;' Sullivan's 'Lectures;' Robinson on 'Gavelkind;' 2 Blackstone's 'Com.;' Wright's 'Tenures;' and for observation on its expediency, Smith's 'Wealth of Nations.' The preference of males to females is not so peculiar. The Jews, Athenians, and Arabians, though not the Romans, gave the inheritance to sons exclusive of daughters. (For the Athenian law of inheritance, see Jones's 'Isæus;' for that of the Jews, Selden 'de Successionibus apud Hebræos.') This is not however the case among most foreign nations at present. The preference of the child of the elder son dead in the purchaser's lifetime to the younger son (which we have endeavoured to show is the necessary consequence of rule 1) has some interesting historical associations. The law on this point seems to have been derived from the civil law, and not to have been settled till after most of the other rules of descent. It was still somewhat doubtful when King John kept his nephew Arthur from the throne by disputing it. (See 2 Bl. 'Com.;' Sullivan's 'Lectures,' lect. 14. In Robertson's 'Charles V.,' vol. i., p. 272, there is a curious story of the trial by combat of this point of law.)

The descent of estates tail (regulated by stat. 3 Edw. I., c. 1) differs from that of fees simple principally in this, that only the descendants of the first donee can inherit; and of these only males claiming exclusively through males can be heirs when the estate is in "tail male:" when it is in tail female (a mode of gift which is quite obsolete), only females claiming exclusively through females. [ENTAIL.] The limited descent of the estates, together with other qualities of them, makes them the best representatives at present existing (excepting indeed copyholds) of the ancient fiefs.

(On the law of descent, as it existed before the late Act, see Sir

Matthew Hale's *History of the Common Law*, chap. xi.; 2 Black. *Com.*, chap. xiv.; Cruise's *Digest*, vol. iii.; Watkins on *Descents*, principally treats of curious points, many of which have ceased to be important. As to the reasons for the new alteration, see *First Report of Real Property Commissioners.*)

DESCENT OF BODIES. [FALL OF BODIES.]

DESERTER, an officer or soldier who, either in time of peace or war, abandons the regiment, battalion, or corps to which he belongs, without having obtained leave, and with the intention not to return.

As the last-mentioned circumstance distinguishes the crime of desertion from the less grave offence of being absent without leave, it becomes necessary, before the conviction of the offender, that evidence should be apparent of such intention. The evidence may be obtained generally from the circumstances under which the deserter is apprehended; for example, he may have been found in a carriage or vessel proceeding to a place so distant as to preclude the possibility of a return to his corps in a reasonable time; or letters may have been found in which an intention to desert is expressed; or some offer may have been made by him of enlisting in another corps, or of entering into some other branch of the service.

The civil courts of law, in this country, have ever had authority to try offenders accused of desertion; but they have long since ceased to exercise such authority, and they now interfere only in the rare case of an appeal from the decision of the court-martial which is held for the purpose of investigating the charge and awarding the punishment. The latter courts are permitted the exercise, to a certain extent, of a discretionary power in proportioning the punishments to the degrees of criminality in the accused; and such a discretionary power is generally considered more likely to promote the ends of justice than the stern rule pursued in civil courts, where, as the jury see no middle course between a certain degree of punishment and entire acquittal, the criminal frequently escapes through their compassion, because the punishment appears disproportionate to the crime.

The practice of deserting from one regiment or corps, and of enlisting in another, either from caprice or for the sake of a bounty, having been very frequent, a particular clause has been inserted in the Articles of War, in order to prevent this abuse. It declares that any non-commissioned officer or soldier so acting shall be considered as a deserter, and punished accordingly; and that any officer who knowingly enlists such offender shall be cashiered. And notwithstanding that such re-enlistment is unlawful, the soldier who afterwards absconds from the corps is punishable as a deserter; and upon any trial for desertion, any desertion previous or subsequent to that for which the prisoner is being tried, if duly stated in the charges, may be given in evidence against him. Any officer or soldier who may advise or encourage another to desert is also punishable by a general court-martial.

Absconding from a recruiting party after having received the enlisting money is, after the expiration of ninety-six hours, declared to be desertion, although such recruit, in consequence of his absence, has not been attested. And an apprentice who enlists, representing himself as free, if he afterwards quit the corps, is esteemed a deserter unless he deliver himself up at the expiration of his apprenticeship. Persons who fraudulently confess themselves to be deserters are liable to serve in any of her Majesty's forces as her Majesty shall think fit to appoint, although such persons have not been actually enlisted as soldiers; or they may be convicted and punished as rogues and vagabonds, or charged with obtaining money under false pretences, and the confession and receiving subsistence as soldiers by such persons are made evidence of the false pretence.

A non-commissioned officer or soldier who simply absents himself from his corps without leave is exonerated from the graver part of the charge, if any circumstances can be adduced from which it may be inferred that the absence was intended to be but for a short time. Such circumstances are: goods of value being left behind; the occupation in which the absentee is found to be engaged being in its nature temporary; an intention of returning having been expressed; or again, the offender suffering himself to be brought back without resistance. Simple absence without leave is referred to regimental courts-martial merely, and these award the punishment discretionally.

The Mutiny Act authorises general courts-martial to condemn a culprit to death, should his crime be found to deserve the extreme punishment; in other cases they may sentence him to a term of penal servitude not less than four years, or to a term of imprisonment, or to corporal punishment not exceeding fifty lashes with imprisonment, and, in addition thereto, the loss of additional pay, or good conduct pay, or pension, to which he might have been entitled.

DESERTS. This word is of very vague signification; it is used generally to designate an uninhabited place, a solitude, and in this sense is equally applicable to the fertile plains watered by the Marañon and the sandy wastes of Libya. It is, however, more exclusively appropriated to sandy and stony plains.

Siliceous sand, to which the term most commonly applies, has been originally produced by the disintegration of the crystalline rocks, or by the mechanical comminution of flint itself, each particle being a fragment of quartz or of flint. Among geological changes always proceeding is the re-aggregation and consolidation of these grains into *sandstone*, which, under the continued action of subterranean heat, becomes metamorphosed into quartz-rock; and this also, in the lapse of ages, may itself become disintegrated, and return to sand again. Sand is of great importance to man, by reason of the fertility which its admixture with clayey soils procures, and by the innumerable uses to which it is applied in the arts. Clays themselves consist of silicate of alumina mingled with silica in a still more minute state of division than that of sand, resulting from the chemical decomposition of felspar, and of other minerals entering into the constitution of rocks. Calcareous sand originates sometimes in the disintegration of limestone rocks, more rarely in the chemical precipitation of carbonate of lime, but most frequently and abundantly, as in much of the sand of the sea and of rivers, in the comminution of corals and the broken shells of mollusks, crustaceans, echinoderms, and other marine or aquatic animals, the hard parts of which consist of carbonate of lime, mingled with the entire shells of foraminifera and minute mollusks. Of this last description of calcareous sand, that of Bermuda is a remarkable example. In many instances siliceous and calcareous sand, and the latter of several or of all kinds, are mixed together. The siliceous is the most permanent, calcareous sand being soluble, and in fact constantly subject to solution, in rain- and in spring-water charged with carbonic acid. The sand of deserts is characteristically (though not exclusively) siliceous, such sand being the most abundant because siliceous rocks predominate in the known crust of the globe, and silica is the most abundant earth in nature.

It was here remarked in this article, as originally published, that "in considering the vast seas of sand which cover such an amazing proportion of the earth's surface, we are tempted to believe that there is too much of it, and that it had been better if in its stead were rich meadows and arable land; but since deserts exist, we must remain persuaded that they are necessary to the general economy of the globe."

But there may be too much of sand, and it may be true that it would be better if in its stead there was land susceptible of cultivation, and yet deserts may be necessary to the general economy of the globe, as it at present exists. We have no *à priori* knowledge of the true order of nature; and, besides, deserts, as we shall presently find, constitute merely one term of the series of forms which the actual surface of the earth has to take during the ceaseless mutations which preserve it in a fit condition for the support of organic existence, and finally of man himself.

A general view of what may be termed the geological philosophy of deserts was given by Dr. Ami Boué, in his explanatory memoir of his geological map of the globe, communicated to the Association of German Naturalists at Gratz in 1843, and read also to the Geological Society of France in the following year, and published in that society's 'Bulletin,' second series, vol. i., pp. 296–371 (Deserts, pp. 326–327). With some corrections and additions, the following statement of this view is derived from Dr. Boué's memoir, as given in a condensed form in Keith Johnston's 'Physical Atlas.'

Among the facts of physical geography of greatest importance towards deciphering the geology of a country, we must rank the locality of *deserts*, or of places where water is rare and vegetation almost or wholly wanting. Deserts, properly so called, infallibly point out districts of the globe into which, at a comparatively recent geological epoch, our present seas were prolonged in great gulfs or straits, or which were occupied by actual *mediterraneans* that have now disappeared wholly or in part, and which gradually changed into fresh-water lakes previous to their escape or entire drying up. [Salt-water lakes, however, have in most cases, if not in all, been an intervening term, and in many instances the only one, as is evident from some of the North African and Persian deserts, among others.] It is, in fact, a physical impossibility that a true desert can expose any *ancient* formation; for every district of that description must sooner or later have been covered by a more modern deposit, more or less fit for sustaining vegetation. It is undisputed that our marine sandy beaches are the only formations now in progress at all identical with deserts; and that it is only the tertiary formation, whether of salt or fresh water, and especially the strata of the arenaceo-cretaceous system, which, by means of the variety of sands, gritstones, limestones, and clays which they include, can originate expanses of sand *interspersed with fertile oases.* These facts suffice to demonstrate the modern origin of deserts in general, and fix, also, in Dr. Boué's opinion, the comparative age of the red and white sandstones of Northern Africa. We deduce, further, he continues, that the formation of a desert presupposes, the vicinity of certain strata or rock-masses, the presence of certain marine currents, and especially a position between great ancient chains of mountains which the water could abrade, in order to form, with the siliceous portions of their structure, either extensive alluviums or strata of sandstone easily disintegrated. To apply these conceptions: we find in Egypt, in Nubia, in Dongola, towards the south of Sahara, in the regency of Tripoli, in Arabia Petraea and Arabia Felix, and in Persia, the inferior cretaceous formation giving rise to moving sands and to rocks of friable sandstone, like those seen at Mans and in Saxon Switzerland; whilst in the rest of Sahara and of Persia, in Egypt, in Mesopotamia, on the banks of the lower Indus, in Central Asia, and Western Australia, the tertiary strata, or even the alluviums, have the chief share in the production of oceans of sand interspersed here and there with saline efflorescences. Other strata or rocks are observed in deserts, on account of the tendency of the moving soil of the latter to invade and cover up everything which does not oppose such domination, either by its elevation above the general level of the plain or by means of its waters; and this is the reason why a variety of rocks have been supposed to be originally connected with deserts, over which they have in reality merely extended their sands derived from the sources already stated. Thus, on the two borders of the Red Sea, granitic rocks, as well as crystalline schists and cretaceous or tertiary limestones, form a constituent part of the soil or substratum of the deserts. This also appears to be the case with some parts of the Asiatic desert of Kobi, and with the few deserts proper of South America, such as that of Atacama, covering crystalline schists. At the eastern base of the Rocky Mountains, in North America, deserts without water have also been produced, it is said, by the disaggregation of sandstones of uncertain age. Still, of course, the sands of deserts must always rest on some other geological formation, like the sandy beaches of the present day.

We proceed from the geology to the physics and meteorology of the subject. Professor Tyndall ('Phil. Trans.,' 1853) having found that there are the strongest experimental grounds for the belief that silica possesses a higher conductive power for heat than some of the metals, and shown that the average conducting power of wood may be taken at 12°, while that of silica is 90° (according to the deflections of the galvanometer employed in his method of measuring that power), remarks that the part played by silica in exercising an influence upon climate has hitherto had no particular importance attached to it; and, having also cited the former conclusions of De la Rive and De Candolle relative to the influence which the feeble conducting power of wood must exert in preserving within a tree the warmth which it acquires from the soil, proceeds to contrast, in exemplifying the functions in nature of silica, two regions overspread with the former and with the latter respectively. "Let us consider for a moment the progress which takes place from sunrise to the hour of maximum temperature in a region overspread with forests, and compare it with that which must take place in the African desert. In the former case, the heat slowly and with difficulty penetrates the masses of wood and leaves on which it falls; and after the point of maximum temperature is passed, the yielding up of the heat acquired is proportionately slow. In the desert, however, the mass of silica exposed to the sun becomes burning hot as the hour of maximum temperature approaches; but after this is passed the heat is yielded up with proportionate facility. Hence a maximum and a minimum thermometer must, in the latter case, mark a far wider range of temperature during the twenty-four hours than the former. This agrees with observation. In Sahara, to use the words of Mrs. Somerville, during 'the glare of noon the air quivers with the heat reflected from the red sand, and in the night it is chilled under a clear sky sparkling with its host of stars.' Were gypsum, however [of which some deserts consist], the prevailing mineral, it is *a priori* certain that this could not be the case to anything like its present extent. . . . . A cube of the latter substance, examined in the usual manner, produces a deflection of 19° only. It is scarcely superior to wood."

Deserts of sand are much more abundant in the Old than in the New World. Almost every plain, even the best cultivated in Europe, contains patches of sand of greater or less extent; but to confine ourselves to *deserts*, properly so called, let us consider the immense surface which they occupy on the ancient continent.

Africa, from its western coast, between the Senegal river on the south and Marocco on the north, to the border of the Red Sea, presents one vast sea of sand, occupying upon an average about 48 degrees of longitude and 10 of latitude, which is but partially interrupted by a projecting part of Fezzan and by the narrow valley of the Nile. This sterile region is divided into two unequal parts; the more considerable, that to the west, being called the Sahara, or Great Desert, and the other, to the eastward, sometimes bearing the name of the Libyan Desert. Both the one and the other inclose a few small fertile spots called *Oases*, which rise in the midst of the sands like islands in the ocean. They serve as a resting-place to the merchants, who, by means of camels, poetically termed the ships of the desert, traverse these dismal regions.

The Desert of Sahara [Sahara, in Geog. Div.] is represented to us as covered with moving sands formed into ridges like the waves of the sea. In the midst of these sands, whose position and aspect are continually changing by the effect of the wind, are dispersed a few rocky hills, and small hollows where the collected waters nourish a few shrubs, ferns, and grasses. The mountains which bound the desert on the west present insulated pinnacles, descending gradually into a plain covered with white and sharp siliceous stones, and which is at last confounded with the sands. At Tegazza, and some other places rock-salt, whiter than the whitest marble, extends in vast beds beneath a stratum of rock.

"During the greater part of the year," says Malte Brun, "the dry and heated air presents the aspect of a red vapour; the horizon seems beaming with the fires of innumerable volcanoes. The rains, which fall from July till October, do not extend their uncertain and momentary benefits to all parts alike. An aromatic herb resembling thyme, the plant which bears the Sahara berry, acacias, and other thorny shrubs, nettles, and briars,—such is the only vegetation which is met with on a few spots in the desert. Rarely is a grove of date-trees or of other plants to be seen. A few monkeys, a few antelopes, content themselves with what little food they can find. The ostrich also inhabits this region in numerous flocks, feeding upon lizards and snails and a few coarse herbs. Lions, panthers, and serpents, often of a monstrous size, add to the horror of these dreadful solitudes. The desert presents no traces of a beaten path, and the caravans that traverse it, directing their way by the polar star, describe a tortuous road in order to profit by the oases, described as brilliant with vegetation, but which probably owe a great part of their reputation to the contrast they form with the absolute barrenness of the desert."

Such is the dryness of the terrible burning wind named Samoom, Samum, or more properly *Samiel*, that it frequently absorbs the water contained in the skins borne by the camels for the use of the merchants and drivers. A last cruise of water has been sold for ten thousand drachmas of gold. In 1805, an akkabah or caravan, composed of 2000 persons and 1800 camels, not having found water in the usual halting places, they all, men and animals, perished of thirst. It is in the desert that is seen most particularly that singular optical illusion termed the *Mirage*. [Mirage.]

Desert of the North-East and East of Africa.—The great sandy region, as we have said, is contracted in one place by the country of Fezzan. To the east and south of this are deserts occupied by the Tibboos, a nation of Berbers; whilst on the north-east the desert of Barca, the ancient Cyrenaica, extends as far as the Mediterranean; both these are continued on the eastern side by the great desert of Libya, which borders on Egypt, forming its western boundary. These deserts differ little in character from the Sahara. To the south, the Libyan desert joins the equally sterile region of northern Nubia; leaving which, and crossing the Nile, we again meet with sandy and rocky tracts, which, from Abyssinia on the south as far as Suez on the north, occupy the whole space between the river and the Red Sea.

A comprehensive induction due—we believe originally due—to the late Edward Forbes, has shown that the Mediterranean and the Red seas are the remainder of a former great Indian ocean and south Mediterranean, which extended to the mountains of northern central Africa, prior to the elevation of the eastern portion of its bed, now forming the land of Arabia, Syria, and Palestine; and probably also, it may be inferred, before the Mediterranean depression had been opened to the Atlantic waters on the west. Agreeably to this view, the Sahara and Libyan deserts, as Forbes further showed, occupy the drained though but slightly elevated bed of the western part of this ancient ocean, extending northward from the mountains to the southern shores of the present Mediterranean. As Dr. Bolle has evinced (Hooker's 'Journal of Botany,' 1852, p. 122) that Fuertaventura, the greatest of the Canarian islands, is a Sahara in miniature, we may add that it must also have extended westward beyond the line of the existing African coast into a part of the area now occupied by the waters of the Atlantic.

Deserts of Arabia.—Passing from Africa to Arabia, we first meet with the sandy hills which form the isthmus of Suez, and separate the Arabian gulf from the Mediterranean, whose coast-line they follow as far as Palestine. Immediately to the south of these sands extends the stony and barren tract known by the name of Arabia Petræa. The reputed Mount Sinai, an imposing mass of granite, is there surrounded by rocks of inferior height, composed in part of sandstone, and inclosing a few fertile valleys producing grapes, pears, and other excellent fruits; but the country in general is of frightful sterility, presenting nothing but a few shrubs of Egyptian thorn (*acacia vera*), which furnishes the gum arabic, with capers, and a few other plants, intermixed with rocks of a blackish granite, of jasper, and of sienite, and plains covered with sand, flints, and rolled stones. There are, however, large herds of gazelles and other game.

On the south, as far as Hadramaut, and bounded on the east by the Euphrates and Persian Gulf, and on the west by Hejaz and Yemen, extend the vast deserts of Nejd and Ahkaff, which produce nothing but a few saline plants. and their general appearance differs little from the deserts of Africa, unless it be that they contain many hilly oases adorned with palms and date trees.

Continuing our route towards the Euphrates, we leave on our left that part of the Arabian desert which bears particularly the name of the desert of Syria, which extends northward as far as Haleb, and in the middle of which the traveller discovers the extensive and solitary ruins of Palmyra, the once magnificent residence of Zenobia.

Desert of Mesopotamia.—Having crossed the Euphrates, we find ourselves in the ancient Mesopotamia, so called from two Greek words signifying *between the rivers*, that is, the Euphrates and the Tigris, and which, in the most extended sense of the name, includes Aljezireh on the north, and Irak-Arabia or Babylonia on the south.

With the exception of narrow slips along the two rivers just mentioned, Mesopotamia is a desert still more horrible than those of Africa and Arabia, of which it may be regarded as the continuation. It is covered with burning sands and sterile gypsum. Wormwood and certain aromatic shrubs are the only vegetation, which, covering immense spaces, banish all other plants. The waters of this desert, mostly all saline or sulphurous, give rise to pestilential miasmata, which remain suspended over the desert till, the equilibrium of the air being disturbed, there is formed that pestiferous wind so justly dreaded in Syria and the neighbourhood, and which suffocates any one who has temerity enough to expose himself to its influence.

This desert, occupied by Arabs living upon plunder, is traversed by the caravans which carry on the commerce between Haleb and Bagdad. Its southern portion, or Irak-Arabia, presents, by reason of the proximity of the two rivers, an aspect quite different from that of Aljezireh. That portion of the plain which forms the ancient Babylonia is covered with alluvium, and, like the delta of Egypt, is periodically inundated. It is an immense meadow, requiring only the hand of industry to be covered as heretofore with abundant harvests, and to become once more the garden of Asia.

Deserts of Persia.—Scarcely have we left behind us these dismal regions, still directing our course eastward, and near the 34th parallel of N. lat., when we meet with the mountains of Kurdistan, covered with forests, and intersected by fruitful valleys.

Having scaled this wall, which forms the eastern boundary of the basin of the Tigris and Euphrates, we find ourselves on the high tableland of Persia, where we again meet with extensive deserts, some of them sandy, such as we have already seen, but more generally of an argillaceous soil; and thus it is that the Persian deserts seem to form the transition between those of Africa and Arabia and the Tartarian *steppes*.

In Persia there are five principal deserts, which occupy about three-tenths of the surface of the country. Of these the first is the great salt desert, which separates Irak-Ajemi from Khorassan, and is about 130 leagues long and 70 wide. On the south it joins the desert of Carmania; on the east it unites to the province of Khorassan. Its soil is a stiff clay, whose surface is covered with a saline efflorescence in some places an inch thick; and its vegetation, as in all the high plains of the country, consists of saline plants, such as the *Statice Tartarica*, intermingled with a few patches of pasture. The three other deserts are those of Kiab, of Meckran, and of Karakoum. The desert of Meckran is in Beloochistan. It is bounded on the south by the sea of Oman, and is separated from the desert of Sinde in Hindostan by the Brahouic mountains and the Indus. It does not belong to the table land of Persia, but to the basin of the sea, of which it forms the northern boundary, or coast line followed by a part of the army of Alexander the Great on its return from India. Its productions differ from those of the Great Desert, and consist of the Indian palm, and the aromatic shrubs of Arabia Felix. The desert of Karakoum is to the north of Khorassan; it is sandy.

Deserts of Grand Tartary.—Descending the Paropamisian mountains which bound Khorassan on the north, and form in that direction the escarpment of the great high-land of Persia, of which the sandy province of Kohistan seems to form the ridge, we enter upon the deserts of Independent Tartary. This country is bounded on the south by the Paropamisus already named, and by the lofty chain of the Hindoo Koosh, of which it seems to be the continuation; on the east by the high mountains which separate it from China; on the north by some ridges, which on the one hand descend from the great Altaic chain, and on the other from the extremity of the Uralian mountains; and on the west by the Caspian. It may be regarded as the north-western declivity of the great central plateau of Asia. It occupies a surface of about 60,000 square leagues, of which the greater half is a desert; for, with the exception of the immediate foot of the mountains and the water-courses, the whole country is condemned to drought and sterility. The saline and sandy plains extend even round the northern part of the Caspian as far as the Don, and, to the east of the Ural, join the steppe of Isim, claimed by Russia.

The country of Khowarezme or Karissum on the south of Lake Aral is now reduced, by causes among which the invasion of the sands is perhaps the most powerful, to the little district of Khiva, which rises like an oasis in the desert, and which a man may ride round in three days.

The greater Bucharia, or Bokhara, is also surrounded by sands to the north and west. The whole of Independent Tartary at the present time perhaps hardly contains a population of five millions,—a proof of the extreme sterility of the soil.

On the south-east of the province of Kohistan, of which we have spoken, is situated Segestan, and the country of the Afghans.

Desert of Afghanistan.—Afghanistan is an extensive country, containing the city of Candahar. [AFGHANISTAN, in GEOG. DIV. It is a vast sandy basin, except in the immediate vicinity of the mountains by which it is bounded on the east and north, and along the banks of the rivers Lhorah and Helmend or Hindamend, which latter traverses it from east to west, and terminates in the Lake Zorah. The land rises on the north-east towards the lofty mountains which sustain the great central plateau of Asia, and from which descend the Indus towards the south-west, and the Ganges to the south-east.

The vast extent of arid deserts which we have just described, scarcely interrupted by the Indus itself, reaches to the very banks of the Hesydrus, the most eastern of the rivers of the Punjab.

From Cape Bojador on the Atlantic to beyond the Indus, the sandy region extends in a curved line of 1400 geographical miles, and, setting aside the fertile oases, is estimated by Humboldt as covering a surface of 300,000 square leagues; and yet, however extensive this tract, which seems condemned to eternal sterility, we have still to consider the great central table-land of Asia, not less arid than what we have just seen.

Deserts of the Great Central Plateau of Asia.—The first country we meet with as we go eastward is Little Bucharia, bounded on the north by the mountain chain of Alak, which separates it from Songaria, and on the south by the Moos Tagh and Great Tibet. On the east it joins Mongolia.

Little Bucharia is tolerably fertile near the mountains, whence descend innumerable streams, which, uniting in the river Yarkand, flow with it into the Lake Lop, having no issue. The whole of the centre and eastern portion of the country is a sandy and salt desert.

Leaving on the north Songaria, which also contains immense arid spots, and whence the river Irtish takes its rise, still continuing our route towards the east, we find the sterile plain extending towards Mongolia, where it opens out to form the vast desert of Shamo, which extends to the Great Wall of China through a length of 500 leagues, rarely interspersed with a few fertile spots.

From the outer slopes of those mountains which inclose and sustain the central plateau, the highest in the world, descend those mighty rivers which, on the one hand, fertilise the great empire of China, and pour the tribute of their waters into the Pacific, and on the other, traverse the widely-extended *steppes* of Siberia to disembogue into the Frozen Ocean.

As for the area of the sandy deserts of the Tartarian table-land, it may on a very moderate computation be estimated at 100,000 square leagues, which, together with the former 300,000 for the African, Arabian, and Persian deserts, and about 100,000 more for the widely-spread sandy and barren tracts in the south of Africa, and sandy patches of Europe, gives a grand total of half a million square leagues of desert in the Old World alone; that is, a surface equal to the whole of Europe, or forty-four times the extent of Great Britain, and this without including the boundless *steppes* of Siberia, or the marshy plains of Northern Asia bordering on the icy sea.

A peculiarity of character in the enormous heat and aridity of the Australian deserts, and which also appears to be extended, though in an inferior degree, to those of South Africa, has a cause purely astronomical—the greater proximity of the earth to the sun at the period of the summer solstice in the southern hemisphere, and winter solstice in the northern; and was pointed out a few years since by Sir J. F. W. Herschel, in his 'Elements of Astronomy' (369), &c. This peculiarity is so remarkable, and would appear to be in its turn the cause of so many phenomena, characterising the physical geography and all the three kingdoms of nature in Australia, that it is requisite to enter more particularly into the subject than might at first sight appear necessary.

For half the year the earth is one-thirtieth part nearer the sun than in the other half-year, and the difference of the sun's direct heating power amounts, in consequence, to one-fifteenth of the whole; but during that half-year, precisely, the earth moves quicker in its orbit, and therefore does not receive any more heat than in the other half-year when it moves slower, at a greater distance from the sun. No inequality therefore exists between the mean temperature of the two hemispheres, but an equal and impartial distribution of heat is accorded to both.

The perihelion of the earth's orbit, however,—the point where the earth is nearest to the sun by 3,000,000 of miles, is nearly at the place of the southern summer solstice, so that the effect of the greater heating power of the sun, owing to the smaller distance of the earth at this particular time, the midsummer of the southern hemisphere, is really to augment the local temperature of places in that hemisphere. This causes the direct impression of the sun's heat in the height of summer, to use the words of the original elucidator of the subject: "The glow and ardour of his rays—under a perfectly clear sky, at noon, in equal latitudes and under equal circumstances of exposure," to be "very materially greater in the southern hemisphere than in the northern.[*] One fifteenth is too considerable a fraction of the whole intensity of sunshine," continues Sir J. Herschel, "not to aggravate in a serious degree the sufferings of those who are exposed to it in thirsty deserts, without shelter. The accounts of these sufferings in the interior of Australia, for instance, are of the most frightful kind, and would seem far to exceed what have ever been undergone by travellers in the northern deserts of Africa."

Facts illustrative of this peculiarity of the Australian deserts, great part of which, in consequence, and on account of their mineralogical constitution, are in the state of compact highly-baked earth, will be found in the relations of their explorers; especially in Capt. Sturt's Narrative of his expedition into Central Australia. He remarks, that the ground was almost a molten surface; and the progress of one of the most recent expeditions is stated to have been terminated by the ground having assumed the condition of the top of a glowing brick-kiln; properly, of a clamp of burning bricks. Capt. Stokes, R.N., has recorded in his 'Discoveries in Australia,' circumstances which evince that the heat acquired from the sun, in the northern regions of the country, is so great, that though the air becomes cooler in the night, from the absence of the solar radiation, the terrestrial radiation, as he observed, is insufficient perceptibly to cool the ground, the heat of which must therefore accumulate until the end of the solstice, and be the immediate cause of the phenomena just noticed. Even at Adelaide, in the province of South Australia, in a higher latitude, the temperature, at the same season, is such as often to threaten, and sometimes to produce, disastrous results; that of the air having been, for example, in February, 1858, for a week or more, at from 110° to 120° Fahr.

---

[*] It must be remembered, that, as if to counteract any possible tendency of this to disturb the general equilibrium or balanced condition of the earth's surface, on which the well-being of the human race and of organic nature in general depends, the *land* being greater in extent in the northern hemisphere, which has its summer solstice in June, the temperature of the whole (as Professor Dove has shown) is greater in that month than it is in December, when the earth is actually nearest the sun.

In South Africa analogous circumstances of weather and terrestrial surface have been observed in Little Namaqualand, half of which is stated to be a dreary waste of desert sand, and the remainder a howling wilderness of lofty rugged mountain chains and peaks, with extensive tracts where no blade of grass or drop of water can be found. Mr. Bell, a recent explorer, though he had travelled in South Africa for twenty-four years, had never acquired, until his recent examination of this region, "any adequate idea of utter desolation." The change of weather was rapid from that accompanying heavy snow up to intense heat; indicating the agency, throughout the seasons, of the same principles, which, as we have seen, govern the diurnal changes of temperature in the deserts of Northern Africa.

The principal desert-plains of America, being of a different character and known by other names, as PAMPAS, SAVANNAHS, &c., are described under their proper heads.

DESICCATION is the operation of drying bodies, and is effected in different modes according to the nature of the substance.

One of the simplest cases is that of drying a precipitate which has subsided in the fluid from which it is thrown down: this may be effected after due washing by transferring it to a glass, porcelain, silver, or platinum capsule, the weight of which being previously determined, that of the substance dried is readily found on weighing. Sometimes substances are dried merely by exposing them to the air; in other cases at a temperature regulated according to the nature of the substances, as at 100° or 212°, in warm chambers, or a sand heat, or at a red or white heat.

The desiccation of precipitates upon paper filters is very commonly effected to a certain extent by absorption, or by placing the filter and its contents upon a piece of chalk or upon a brick; the operation being completed either by exposure to the air, or in any of the vessels and at any of the temperatures above named. In many instances desiccation is performed by means of the air-pump, which is useful in those cases where delicate organic bodies, which would be injured even by moderate degrees of heat, require drying. Mr. Leslie's process consists in placing the substance to be dried (or a fluid to be evaporated) under the receiver of an air-pump, over a basin containing sulphuric acid or some other substance having great affinity for water. The receiver being exhausted, the operation is left to itself. On account of the absence of the air, the moisture is readily vaporised and is quickly absorbed by the sulphuric acid; and the vaporisation and absorption continue till the substance is dry.

Desiccation may be carried on at common temperatures without the process of exhaustion above described; thus a basin containing quicklime with a moist precipitate placed above it, and the whole covered with a jar or receiver, will soon render the precipitate dry. Any deliquescent salt may be substituted in some cases for sulphuric acid or quick-lime; such, for example, as potash, carbonate of potash, and chloride of calcium.

In chemical investigations it is frequently necessary to deprive gaseous bodies of their moisture. The nature of the drying substance employed must depend upon that of the gas to be desiccated: thus ammoniacal gas is absorbed by chloride of calcium, and immediately by sulphuric acid, but potash or carbonate of potash answers well for it. Again, sulphurous acid gas would be absorbed by potash or carbonate of potash, carbonic acid being evolved in the latter case. In fact care must be taken that the desiccator exerts no chemical action upon the substance to be dried.

DESIGN. In the Fine Arts the word design (from the Italian *disegnare*, to draw) is employed in two very different significations. In the first place it is used merely to signify the act of drawing, or representing in lines, the form of any object; in the next place it expresses that combination of invention and purpose which enables the artist to compose a picture or a group, without reference to the material in which it is executed.

The accurate conception of form and beauty is displayed in the most masterly degree in the ancient Greek sculptures; and in the invention of appropriate attitudes, and perfection of physical form, the design of the best Greek sculptors cannot be surpassed. And whilst such works as the marbles of the Parthenon are the safest guides to the young sculptor, they afford also models that cannot be too carefully considered by students of every other branch of art. Of all the existing specimens of painting, the works of the Italian masters display the most consummate excellence in design, especially the Florentine and Roman schools, and among them Raffaelle's in particular. The conception of the story, and the ruling passion of the moment; the selection of forms appropriate to the actors of the story; the invention of appropriate attitudes, not merely for the single figures, but for whole groups, artfully disposed in such manner as to be adapted at once to the freedom of nature and the intention of the artist to assign to each its position according to its prominence in the story; and the perfect execution of the design, placing before our eyes in a palpable shape the inward thoughts of the painter, combine to render the design of Raffaelle's works the most perfect in existence. Michel Angelo's power is more apparent in the conception and execution of forms purely physical, and his design is therefore of a more limited though perhaps hardly less elevated style. A single figure from his unrivalled hand may be contemplated with emotions of admiration and wonder scarcely less than those which we feel when the whole of his greatest work is before us. Raffaelle designed not merely to overawe the spectator with physical vastness, but to elevate him above the visible world. Human suffering, superhuman inspiration, and divine benignity are subjects within the reach of his pencil. These are displayed equally in his cartoons as in his frescoes and oil paintings—perhaps, indeed, even more. [CARTOONS.] The tortured figure of the chastised Ananias, the terrible power inspired into Peter, the prophetic absorption of the apostle near him, pointing with his finger to the source of that power, bring into the design of that one cartoon (the Death of Ananias) the most sublime speculations; and if it be second to the Transfiguration as a picture, it is no less a model of perfection in design,—notwithstanding anachronisms of costume, &c., which it would be absurd in a painter of the present day to repeat.

The student in design may discover the means by which former artists attained their power by carefully studying and thoroughly analysing their works,—namely, the sculptures of Greece and the paintings of the old masters. But it must be study pursued with a view to the enlargement of his artistic powers, not to the accumulation of precedents or the imitation of style. Copying, he must recollect, is at best, as Reynolds expressed it, a delusive kind of industry. He must, however, equally avoid following the implied advice of Reynolds, merely to store his mind with the thoughts of the great masters, and give them forth second-hand as his own. That the greatest poets and painters have borrowed is no apology for an education which recommends only borrowing. To appropriate with justice and effect the thought of another, the borrower must be at least as great as the original inventor. The legitimate object of study, or that part of study which seeks to shorten the process of education, is to discover the mode which other artists have pursued in disciplining their minds, and eyes, and hands, in order to comprehend and express the nature which they had to portray. Art, as has been said already [ARTS, FINE], is creative, not imitative. Every work of Fine Art, to whatever class it belong, is valuable in proportion as it reveals the inner thought, idea, or mental idiosyncracy of the artist; and that course of study, therefore, will be most efficient which prepares the student to give the fullest effect to what he himself has observed in human experience and external nature. The study of the best poets, of histories, and the lives of individuals, of emotions casually displayed in the events of daily life, and in fact everything that helps to teach a knowledge of human nature, and the working of its internal feelings, combined with an accurate knowledge of those external forms which must enter into every composition, will conduce to the development of a power of original design.

DESIGN, IN ARCHITECTURE. Design, together with its meaning of drawing, is often understood to mean the *idea*, rather than the *drawing*, of either a picture or of a building; and people talk of the *design* of either of those classes of art production, as though it meant exclusively the abstract invention, or the original conception, of the artist. There is also a moral sense attached to the word, which is frequently used, in works even which treat exclusively of art, namely, the sense of *intention;* and a man is said to do a particular thing with design, when he does it with a premeditated intention. In the following notice the word will be used exclusively in the primary sense, or that of an equivalent to the art of drawing, as applied to architecture or engineering; the secondary sense will be referred to hereafter under the head INVENTION; and the illustrations to be given will have special reference to the practice of engineering and architectural works.

The scheme, idea, or, as it is more usually termed, the design, whether for an intended building or that of one already erected, is usually shown by means of a series of diagrams or drawings, which, being exact geometrical representations, are therefore too technical and formal to satisfy those who look at them as pictures, besides being likewise in some degree imperfect as separate representations, yet, taken one with another, convey a much more exact and complete notion of the whole, both internally and externally, than can be obtained by any other mode of delineation; because they not only exhibit the actual forms and dimensions as they really are intended to exist, and not merely as they would appear to the eye according to the situation of the spectator; but they also reveal the whole anatomy of the fabric, together with many particulars that are concealed from view in the edifice. Such drawings consist of *plan*, *elevation*, and *section*, besides other *details*, or *parts at large;* and their number will depend either upon the nature of the building, that is, on its being more or less complex, or as it is intended to show it more or less fully.

Although a certain prejudice exists against such drawings, on the score of their being too technical and difficult, they become, when once explained, intelligible enough to any person of common capacity, however ignorant he may be of architecture. To begin with the *plan* (the *plant*, or *plot*, as it is sometimes termed by old writers), as the first in natural order, it being that which must be determined upon before the walls can be raised. The plan may no less briefly than clearly be described as the map of the building; consequently, any one who understands geographical or topographical plans of that kind can be at no loss to comprehend the nature of an architectural one; the latter being a far more exact and less arbitrary and conventional representation than the other class. By means of the plan we distinguish most clearly the exact shape and extent of the building as regards the space on which it stands; the thickness of the walls, the internal arrangement, with the forms, number, and areas of the rooms and passages into which it is divided; and the situation and width of the doors, windows, fire-places, staircases, &c.; the solid and raised parts, such as walls, columns, piers, &c., being shaded, and the voids or apertures in the walls, such as doors and windows, being left plain. For every story of a building there must be a separate plan, although it is not usual in books of designs to give more than those of the ground-floor and the principal floor, above it, from which the arrangement and size of the rooms above them may be tolerably well guessed at, unless there should happen to be some uncommon deviation in such respects from those below. Plans may further be distinguished as simple or detailed: the former are mere *floor-plans*, indicating no more than belongs to the floor and walls, while the latter describe, by means of dotted lines on the floor, the projection of cornices, the compartments of ceilings, or the groining and coffering of those which are vaulted or arched; likewise domes and skylights. Or else, instead of expressing what belongs to the ceiling plane, a plan of this kind is made to indicate the pavement of floors, the situation of statues, sideboards, bookcases, and other pieces of furniture, particularly of beds in sleeping-rooms, the position of which is of material importance. Sometimes, too, plans are given showing the exterior of the roof of the building, with its chimney-stacks, gutters, skylights, dormer-windows, parapets, &c.

Another species of plan is that termed a *block-plan*, namely, a map displaying the general mass of the building, together with its locality, either in regard to other edifices or not, as the case may be; and such plans are an exceedingly useful accompaniment to those already described, because they serve to make us acquainted not only with the structure itself, but with its situation. From a ground-plan alone, for instance, of St. Paul's, all that could be learnt in respect to the last-mentioned circumstance is, that it is insulated, whereas a block-plan would show the precise form and extent of the surrounding area; how confined and irregular it is, and how far it would be necessary to set back the houses in some places in order to reduce the whole to uniformity. Plans of this kind are, in fact, *special* maps laid down upon a larger scale, and therefore more exact and detailed, although less comprehensive than ordinary ones.

An *elevation* (formerly termed an "upright," in Italian *alzata*, in German *aufriss*) may be described as a vertical plan, showing the front or one external face of the building as raised upon the plan; it therefore gives the precise forms and measurements of every part, delineated geometrically according to scale, and not as they appear according to distance or the accidents of perspective, whether depending on the level at which the eye is placed, or as the building happens to be viewed parallelly, or more or less obliquely. When the elevation is a single general plane, as is the case, for example, with the Travellers' Club House, in London, it will not differ very much from a direct front view, the projections being only those of the cornice, the dressings of the windows, &c., which are rendered manifest, and may be measured from their profiles; consequently, an eye unaccustomed to such drawings cannot be puzzled. It is necessary, on the contrary, that a person should understand the principle of geometrical drawing before he can form a correct idea of the subject, and judge what its actual appearance would be, if it consists of several planes or separate elevations placed one by the side of the other, all standing upon the same line, and without their returns or the planes perpendicular to and connecting them together, being shown; because, unless the plan is also seen, the shadows alone serve to indicate what parts project and what recede beyond the general line of the front, and in what degree they do so, the shadows being at an angle of 45°, whereby they are made equal to the projection of the part which occasions them, beyond the plane or surface they are thrown upon. This may be easily exemplified by St. Paul's Cathedral: in a geometrical elevation of the western front, the shadowing informs us (without referring to the plan) that the columns in the centre are at some distance from the wall behind them, yet do not form a projecting portico (or porticoes, one above the other); for that would cast a shadow from itself on the building; but that the parts behind the columns recede inwards. Again, we should perceive the whole of the cupola just as if it were immediately over the front, and *between* the two western towers. The only thing to indicate the contrary is, that the shadows would be less forcible, and a tint would be thrown over it, by way of expressing distance; and although, independently of that, no architect would imagine it to be so placed, yet it would be impossible to determine the precise distance from the front, there being no shadow cast upon it by any other part of the building. Consequently, this would remain to be ascertained, either from the ground plan or from a lateral elevation of the building, in which the cupola would be shown above the transept. One particular in which elevations differ materially from other drawings and from the appearance of the objects themselves, is, that no distinction is made between curved horizontal lines and straight ones: so that whether the part be a plane or curved surface, can be understood only from the shadowing, unless there happens to be something that assists in denoting curvature of plan. Thus, the mouldings of the base of a column are all straight lines; consequently, without shadow to express rotundity, we could not determine whether they belonged to a flat or round surface, unless the shaft be fluted, in which case the flutes will diminish in width, according to their distance from the centre, as may be seen by referring to the cuts in the article COLUMN. So likewise, in respect to a tower without either apertures or vertical lines regularly placed, we cannot judge whether it be circular or not; whereas, if there be either of those descriptions of lines, they suffice to show that the surface is curved, although represented only in outline; because the apertures and the spaces between them would become narrower in proportion as they are more distant from the centre, and their *reveals*, or inner surfaces, would appear. Still, without shadow, we should not know whether the surface was convex or concave, except by referring to the plan, or by the nature of the subject, there being no difference between the two as regards outline alone. This will be obvious when it is understood that the elevations of curved surfaces are projected, as it is termed, from their plans, by lines drawn perpendicularly to the geometrical plane of representation, which determine where the vertical lines to be shown in the elevation will fall, and the distances between them; consequently, whether the elevation be projected from a convex or concave plan, the result will be the same. When no curved parts occur in the elevation, the process just described is superfluous, because the measurements may be taken at once from the plan. The same method, however, it should be observed, is employed for polygonal figures as for circular or curved ones. Thus, of an octagon three sides would be shown in elevation: yet, although of the same width, the two diagonal or oblique ones will appear narrower than that seen directly in front; and the same applies to all oblique surfaces, let the angle they are placed at be what it may; and to such likewise as are oblique to the horizon as well as to those which are vertical. Hence a roof terminated by gables or pediments at the ends of the elevation will, as regards outline, be drawn as an upright plane, and the sloping lines of the pediment will appear vertical.

Notwithstanding, however, these circumstances, which are apt to perplex those who are prejudiced against geometrical drawings because they are not satisfactory as "pictures," a person at all accustomed to them is so far from being in danger of misconceiving them, that it would require an effort on his part to imagine the objects other than what the drawings are intended to express—to fancy a semi-circular projection to be a plane, or the profile of a pediment to be upright.

Nevertheless, although the whole may be perfectly well understood, it is not always that sufficient allowance is made, even by architects themselves, for the great difference which sometimes occurs between an elevation and the building itself; or that the real effect is duly considered beforehand. Recourse is therefore occasionally had to what is termed a *perspective elevation*—a kind of conventional representation, partly geometrical, partly perspective, and combining in some degree the advantage of both modes, although strictly neither of them. As in elevations of the usual kind, the building is shown exactly parallel to the picture, with the point of sight precisely in the centre, at the proper height from the ground, and as far as regards the first or principal plane, is treated as any other geometrical drawing; but the parts beyond this plane are thrown into perspective so as to show the sides of projections, the soffit of entablatures, the ceiling and pavement within porticoes, and how much of a dome or other part of the structure, standing back from the front, would be concealed from view, at a given distance. It may be further observed, that elevations, both those of the above description and such as are strictly geometrical, have very frequently a pictorial character given them, not only by colouring as well as by shadowing, but also by the addition of sky and background. Yet it would be better were such accompaniment no more than what is just sufficient to relieve the building, instead of being extended over the whole drawing, and carefully worked up; because it is calculated to seduce the eye, while, by making too great pretensions to the character of a picture, it causes the elevation itself to appear offensively formal and unnatural. In fact, *outline* elevations (which mode is now generally adopted in modern architectural publications, especially foreign ones) are preferable to those which are shadowed, as they exhibit all the forms more distinctly, and admit of being measured with much greater exactness. They do not, indeed, convey any notion of effect; yet that may very well be dispensed with in such drawings, particularly if they be accompanied with perspective views.

We now come to speak of *sections*, which are for the interior what elevations are for the exterior of a building. A section or profile (in French *coupe*, Italian *spaccato*, German *durchschnitt*), is a plane cutting through the structure on some line of its plan, and showing the thickness of the walls and floors, the heights of the rooms, the forms and profiles of ceilings, whether plain or decorated, flat, coved, or arched; also the exact forms of domes and skylights. In fact it exhibits all the separate elevations of the rooms intersected by such plane, that is, the elevation of that side of them which faces or lies behind the plane of representation. In addition to the particulars just enumerated, we are by this means made acquainted with a variety of others, in regard to which a plan cannot be made to afford any information. The thickness of the walls may be ascertained by the plan as well as by a section; so also might the height of the rooms be expressed in the former by means of figures, as the other dimensions generally are; and the form and size of the windows may be learned from the elevations; still we should not know what are the heights of the doors, how they are pannelled and decorated, nor what is the form of the chimney-pieces, &c.; nor be able to judge so well of the general proportions of the apartments. Besides which, sections may be made to show much more than what belongs to the architecture alone, for there are many instances in which furniture, pictures, and other decorations and fittings-up, are introduced; and unless this be done, a section is apt to have a naked appearance, except the architecture itself be particularly interesting and rich. For detailed and filled-up sections it is usual to employ outline, with the walls and floors shaded, the former as more solid being made much darker than the latter. When, on the other hand, the elevations of the rooms themselves are shadowed, the thickness of the intersected walls, &c., are left white, in order to prevent confusion and exhibit the profiles better. It should be observed, too, that in sections of this latter description, it is the practice to throw a shadow from the side walls and ceilings of the rooms, as if it were a model of the building really cut through; thus producing an effect both disagreeable and unnatural, and by no means assisting towards rendering the representation more intelligible. Indeed indispensable and interesting as they are, sections are a far more conventional mode of drawing than elevations, because they represent a building as it never can be seen at all, except where the front of a house has been taken down for the purpose of rebuilding it, while the floors and partition-walls are left standing; in which case any one may obtain a good idea of the nature of a section, but of one seen in perspective. Besides general sections showing the whole of a building from top to bottom, there are frequently partial ones, showing only the rooms on one floor, or even a single room, when it is desired to show it on a larger scale than could conveniently be done any other way. Or instead of this, recourse is sometimes had to a plan of the room with each of its elevations or sides drawn around it, as if laid down flat on the ground, by which means the whole of the apartment is described; for the ceiling may be represented on the plan itself. Horizontal sections again are occasionally made use of, in order to show more accurately than can be done upon a plan, not only the ceiling and its ornaments, but the soffits of entablatures, of window recesses and door-cases, also the capitals of columns and their projection.

Although not in general use, there are likewise many other modes and combinations which deserve to be pointed out. One of them is that of elevation and section united; that is, one half the drawing shows half the elevation, which, as far as understanding it, fully answers the purpose of an entire one; while the other half shows half the section. Another is that of *sectional perspective view*, which, while it serves the purpose of a section in regard to showing the exact form, profiles, and measurements, on the first plane, intersecting the structure, gives also a picture of its interior just as it would appear in any other drawing of the kind; the only difference being, that in this case the drawing extends beyond the interior, while in other views it is bounded by and confined within it. It is hardly necessary to observe that such a mode is suited only for showing a single space, and not one divided into separate rooms. It is exceedingly well calculated for displaying the interior of a portico, as it admits of the situation of the columns in front being shown by the foreground being made a *perspective plan*.

Besides the usual plans, elevations, and sections, there must likewise be *details* or *parts at large*, answering in some respect to what are termed working drawings; since without these we judge only of the general design, but not of its minutiæ and finishing, whether belonging to decoration or construction:—and far more may be learned, and that too more satisfactorily, by studying a single good example thoroughly, than by looking at many which are only imperfectly described. It is therefore to be regretted that published designs, unless they happen to be those of actual buildings, are so exceedingly defective in this respect, generally showing no more than a couple of plans with one or two elevations, while, although so very essential, sections are entirely omitted. In order to illustrate a subject properly, not only should there be a plan of every floor and an elevation of every side, but sections, both longitudinal and transverse, and as many of each as the nature of the plan may require.

Having done thus much to show the whole anatomy of the structure, we may then provide perspective views both of the exterior and principal parts of the interior, in order to show the character and effect, which, without such drawings, can be judged of only piecemeal, and inadequately even by those who perfectly understand the others. Yet however satisfactory as a representation, a perspective view of an interior must still leave much to conjecture, as one of the sides or ends of it cannot possibly be shown, while of the others two will be more or less foreshortened, so that if there be deep receding parts in them, they can be but imperfectly seen,—perhaps may be quite misunderstood; or can be well understood only by the aid of plan and section. In many cases, therefore, an interior would require two or even more perspective drawings in order to show it completely. But with every part of the building thus fully made out and described in drawings, the whole may be understood as well, in some respects even better, than by a model of it; for besides that the latter can do very little towards showing the interior—certainly not its effect,—there is this drawback attending it, that it conveys no idea of situation or locality, and that, instead of the eye being confined either as to due distance or height, it views it from points from which the building itself can never be seen under any circumstances. Neither has it the accompaniment of sky, background, foreground: a model exhibits the mere building alone—as it is, certainly, yet not as it appears; for it is seldom any attempt is made to give the proper local colouring—at least to do more than merely hint at it. By means of perspective views, on the contrary, provided they be sufficiently numerous and judiciously chosen, and not deceptively embellished with effects of rare occurrence, we may obtain a most accurate idea both of the architecture and of all its local accompaniments and accessories, whether favourable or the contrary. Of *bird's-eye* views of buildings we have said nothing, both because they are now seldom made use of, and because we consider them not only most awkward, disagreeable, and unnatural representations in themselves, but as altogether superfluous, if a building is properly described by the other modes, or even by a block-plan and elevation alone.

DESIGN, SCHOOLS OF. [Science and Art, Department of.]

DESPOTISM. [Monarchy.]

DETACHMENT, in military affairs, is a portion of an army or body of troops detached and sent on a particular service. It may consist of thousands of men, cavalry, artillery, and infantry, or a small portion of a company. The former description of detachment, namely, one that will materially weaken the main body of an army, has often been made with good results, and more often with bad ones; it is in fact one of the most difficult and dangerous problems of strategy, depending, as it does, for its success in many cases on the fortuitous concurrence of many eventualities, the non-foreseeing or reversal of any one of which may upset the best laid plan for the co-operation of the main body and its detachment, and allowing each to be taken in detail, lead to the most disastrous results. Jomini, in his 'Précis de l'Art de la Guerre,' treating this as a mixed operation which partakes at once of strategy and tactics, has laid down very clearly nearly all that can be said on the subject, and to his work the reader is referred, as the following article can only pretend to exemplify some of the most open advantages and defects of detachments.

A general is so often compelled by necessity to make detachments, and on the proper handling of them so much depends the success of a campaign, that one cannot but consider this one of the most important and delicate operations of a campaign. "En effet," says Jomini, "si rien n'est plus utile qu'un grand détachement lorsqu'il est fait à propos et bien combiné, rien n'est plus dangereux quand il est fait d'une manière inconsidérée." The very employment at all of a detachment, except in those cases where it is meant to rejoin and co-operate with the main body at the critical moment of a general action, appears to be contrary to the cardinal principle of strategy and tactics to act with superior forces on the decisive point, and yet there are circumstances under which they are indispensable. The general employment of detachments may be classed under the following heads:—

1. The employment of great detachments, almost separate armies, not in the principal zone of operations, but with the object of creating diversions on more or less essential points. This seems the most indefensible use of detachments, one in which English forces have often been employed, and which, against a great general, such as Napoleon, were utterly thrown away; for instance, in 1805, Napoleon occupied Hanover and Naples. An English and Russian army was formed to drive him from Italy, and an English, Russian, and Swedish army to operate in Hanover. Nearly 60,000 men being employed in these two detachments, Napoleon, disregarding them, ordered St. Cyr to join Massena on the high Adige, where, based on the Adige and Mincio, and in a very strongly fortified position, he was to oppose the Archduke Charles, whilst Bernadotte quitting Hanover joined him in time to take part in those overwhelming operations about Ulm and Austerlitz, after which Italy and Hanover were easily retaken. On the other hand, a detachment of this description would, in the civil wars of 1793, Jomini considers, have produced decisive results if thrown into La Vendée.

2. Large detachments in the zone of operations to cover important points, to carry on sieges, to mask fortresses, or to protect lines of operations.

These may be termed permanent detachments, acting perhaps during a whole campaign in their own zone of operations. There are again temporary large detachments formed for any of the following special objects bearing immediately on the grand objects of the campaign:—

1. To act on the lines of operation of an enemy and oblige him to retire, or, if retiring, to cripple his retreat.

2. To keep in check or retard the junction of a large detachment of the enemy with a smaller force, and thus allow an overwhelming force to be thrown on the decisive point, or to protect the junction of a detachment.

3. To seize or protect a large convoy, as was effected before Pultowa by Peter the Great against Charles XII., whose detachment of protection lost its way, entailing the loss of Lowenhaupt's convoy, thereby entailing his defeat.

4. To draw off an enemy's attention while an operation is being effected in a different direction, or to mask a fortress and contain its garrison for a short time. Thus Moreau, in 1800, while he himself marched on Stockach, deceived Kray by sending his left wing from Kehl to Rastadt, which then rejoined him by Fribourg.

5. A detachment made almost on the field of battle to act on the flank or rear of the enemy, as at the battle of Vittoria, where the troops under General Graham, though under very unfavourable circumstances for unity of action, from the difficulty of the ground, yet managed to co-operate with great nicety.

However enticing and important these various objects may appear to the general of an army, history has proved that the success of a campaign never depends on such isolated and secondary events, but on the grand decisive actions, or, as at Ulm, merely manœuvres about the decisive point. Hence, it follows that when these approach, exertion should be made even to the running some risks to recall and concentrate the whole available forces. A good example of this is given by Jomini. In 1797, Napoleon, obliged to leave a corps of 15,000 men in the valley of the Adige to contain the Tyrol while he advanced on the Noric Alps, preferred making this corps rejoin him at the risk of compromising for the time his line of retreat, to affording the opportunity, by leaving his army disuuited, of having them beaten in detail. Persuaded that he would be victorious with his army united, he considered the temporary presence of some detachments of the enemy on his communications of little moment.

Small flying detachments, whose absence does not materially reduce the strength of an army, do not however come under this category; they may and have often been employed with great advantage, when under intelligent daring officers, partisan leaders, and more especially with irregular troops, whose presence with the army itself would be of little use. The guerillas in the Peninsula afford a good example, entailing endless annoyance to the enemy in cutting off convoys, intercepting orders, and reducing his available forces by compelling him to use large bodies of men in these harassing duties.

DETERMINATE, a word applied in mathematics to those problems which have one answer only, or at least a certain and finite number of answers. Thus the problem, "given the base of a triangle, and the sum of the other two sides, to construct the triangle so that its vertex may be on a given straight line," is determinate; for the number of ways of solving it cannot exceed two. But if we omit the condition that the vertex is to be upon a given straight line, and merely require that a triangle shall be constructed having a given base, and two other sides of a given amount of length, the problem becomes indeterminate; that is, has an infinite number of solutions. The peculiarities of this subject—namely, determinate analysis—are not striking; it is to the word INDETERMINATE that we must look for the most characteristic points of distinction.

DETINUE is the form of action prescribed by the English law for the recovery of goods and chattels which have lawfully come into the possession of a defendant either by delivery or finding. It does not lie for real property, but for mere personal chattels, except only deeds and charters. [CHATTELS.] In this action the plaintiff recovers either the thing detained, or if the thing cannot be had, the value of it, with damages for the detention. In order to enforce the redelivery of the specific chattel, a special writ of execution has been provided, by the Common Law Procedure Act, 1854. The action of detinue is similar to the actio depositi of the civil law, and is identically the same in its properties, process, circumstances, and forms as the action of debt, with this difference, that one is for the recovery of a chattel, the other of money. In order to ground an action of detinue, which is only for the detaining, these points are necessary · 1. That the defendant came lawfully into the possession of the goods. 2. That the plaintiff have a property. 3. That the goods themselves be of some value. 4. That they be ascertained in point of identity.

DETONATION is a chemical term employed to express combination or decomposition which occurs with noise and frequently with combustion. It may take place between bodies in very different states, as between gaseous bodies, a gas and a solid, &c. One of the simplest and most powerful cases of detonation is that which happens when two volumes of hydrogen gas and one volume of oxygen gas are mixed, and fired either by the taper, electricity, the action of spongy platinum or sudden compression; in this case the detonation is loud, and the result of the chemical action is water formed by the union, in the proportions stated, of the gases above mentioned.

The sun's rays falling suddenly on a mixture of hydrogen and chlorine gas cause them to detonate and combine with the formation of hydrochloric acid. Detonation also occurs when phosphorus, mixed with chlorate of potash or with nitrate of lead, &c., is struck upon an anvil. And there are certain combinations of metals which detonate or fulminate, by slight friction, by heat, or by electricity; such are the ammoniurets of silver and gold, fulminate of silver and of mercury. The chloride of nitrogen and the iodide of the same element are very powerful detonating bodies. In some cases, as has been mentioned, the result of detonation is combination, as when oxygen and hydrogen unite to form water, chlorine and hydrogen to form hydrochloric acid, &c. In other cases decomposition occurs and is the result of detonation. Thus ammoniuret of gold is separated into metallic gold, and other products; iodide of nitrogen separates into its elements, the iodine appearing as a purple vapour, and the nitrogen assuming the gaseous form.

DETRUSION, FORCE OF. [MATERIALS, STRENGTH OF.]

DEUCA'LION, a prominent personage in the mythical traditions from which Greek history sprung up. He is represented as the son of Prometheus and Clymene (Schol. Pind. 'Olymp.' ix. 72), or of Prometheus and Pandora (Strabo, ix. p. 443, and others), and is sometimes called the father (Thucyd. i. 3), and sometimes the brother of Hellen (Schol. Apollon. iii. 1086), the reputed founder of the Greek nation. The seat of his authority was Phthia, in Thessaly, from which, according to general tradition, he was driven to Parnassus by a great deluge (Apollodorus, i. 7, § 2), which, however, according to Aristotle ('Meteorol.' i. 14), occurred between Dodona and the Achelous. But whatever may have been the scene of Deucalion's deluge, the old traditions represent it merely as a local one; and it was not till the time of Ptolemy Philadelphus, when the Hebrew scriptures became known to the Greeks, that some features borrowed from the universal deluge of Noah were incorporated into the story of the Thessalian flood. (See Clinton's 'Fasti,' vol. i., p. 43, note.) The legend is well known to the readers of Ovid ('Metam.' i. 375, foll.), which tells how he and his wife Pyrrha repeopled the wasted district by throwing stones behind him on Mount Parnassus, in obedience to the injunctions of the oracle of Themis, which directed them to cover their heads and cast the bones of their mother behind them. Strabo says that two small islands on the coast of Phthiotis were called Deucalion and Pyrrha. The date assigned to Deucalion by the Parian Marble is 1548 B.C., and by Eusebius 1541 B.C.; but the stories connected with his history are so manifestly fabulous, that doubts as to his actual existence are unavoidably entertained, and it seems reasonable to conclude that he was a mere personification. It must be confessed that there are no etymological grounds for thinking so, as appears to be the case more or less with the early kings of Attica ('Philolog. Mus.' ii., p. 345, foll.), for the name Deucalion seems to signify nothing more than "the illustrious" (Hesych. sub v. δευκός), and is a possible name for a real person; it was also borne by a son of Minos II. (Apollod. iii. i. 2.)

DEUTERO'NOMY, the fifth book of the Pentateuch, or five books of Moses. The Hebrew title אלה הדברים. ēlleh haddevarim, "These (are) the words," consists as usual of the commencing phrase, a mode of appellation similar to that adopted in technically quoting a legal instrument. Among the Rabbins it is also called *sepher tuckhuth*, "the book of reproofs," or "denunciations," of which there are many, as in chaps. iv. ix. xxviii. xxx. xxxii; and *Mishneh hattorah*, the repetition of the law, a restatement being made in this book of the the Mosaic laws contained in the preceding books of the Pentateuch. The Greek title *Δευτερονόμιον*, *deuteronómion*, given in the Septuagint translation, is composed of two words signifying "second" and "law." By the Jews this book is divided into ten paraschioth, or chapters. In the translations the number of chapters is thirty-four. The events directly related by the writer are comprised in a period of five lunar weeks, from the commencement of the eleventh month to the seventh day of the twelfth month of the fortieth year of the wandering of the Israelites in the wilderness, after their departure from Egypt. The book is generally considered to have been written A.M. 2553, or 1451 B.C., by Moses, in the last year of his life, when at the age of 120, and in the plains of Moab (i. 5; Numbers xxxiii. 50, xxxv. 1), near the ford of the Jordan, where the Israelites afterwards crossed over into Canaan. The opinion which attributes the authorship of this book to Moses is attended with some difficulties which have induced Eichhorn and other learned commentators to assign a much later date to it than the age of Moses. These have been ably met however, and the numerous notices of nations with whom the Israelites had come in contact, but who subsequently disappear altogether, afford strong indications of the Mosaical origin of the book. The concluding chapter, which gives an account of the death of Moses, and of his having been buried by God, is believed by most but not by all of the commentators to have been not written by Moses, for some considered this account as a prophetic one, related in the past tense, a practice not unusual among the Jewish prophets. This last chapter is supposed by others to have been jointly or rather successively supplied by Joshua, Samuel, and Esdras. Besides an historical repetition from the preceding books of the Pentateuch of the events which passed throughout the forty years from the departure from Egypt, the book contains a complete recapitulation of the moral, ceremonial, and judicial law, exhibited in the preceding books of Exodus, Leviticus, and Numbers, with alterations, and some additions; as, for instance, that of the law (xxi. 18) which requires the parents of a stubborn son to lead him forth to be stoned to death by his fellow citizens. The first thirteen verses of chap. xxviii. proclaim the blessings promised to the observers of the the law, and the fifty-five following verses recite the curses on the disobedient. The last twelve verses of the xxvii.th chapter contain the twelve curses which serve to compose the Commination of the English Liturgy. The passages in chap. xviii. 15, 18, 19, are considered as prophetical of the Messiah, on the authority of Acts iii. 22, 23; and vii. 37. Chap. xxxii. consists of the last song of Moses, the poetry of which, in the opinion of a very competent judge, Bishop Lowth, is singularly magnificent. Dr. Adam Clarke remarks, that "very few parts of the Old Testament Scriptures can be read with greater profit by the genuine Christian than the book of Deuteronomy," which is to be considered as correlative with St. Paul's Epistle to the Hebrews. In Wilson's 'Archæological Dictionary,' article *Law*, a valuable tabulated exhibition is given of the whole Mosaic Law, in three classes, moral, ceremonial, and political, with the places of references to Exod., Levit., Numb., and Deut. Dr. Adam Clarke concludes his commentary on the book with six elaborate chronological tables, for which he deserves the thanks of every biblical student. The 'Biblioth. Brit.,' by Watt, contains a numerous list of sermons and commentaries on Deuteronomy.

(Eichhorn's *Einleitung in das Alte Test.*, abtheil ii.; Poli, *Synopsis Criticorum*, tom. i.; Calmet's *Dict.*; Horne's *Introduc.*, vol. iv.; *Horæ Mosaicæ*, by Rev. G. Faber; *Lectures on the Pentateuch*, by Dr. Graves; *Comment. on the Mosaic Laws*, by Michaelis, trans. by Dr. Smith.)

DEUTOXIDE. A chemical term applied to compounds of oxygen, containing two equivalents of oxygen to one of some other body. It is synonymous with *binoxide*. [Chemical Nomenclature.]

DEVASTAVIT. [Executor.]

DEVELOPMENT. (Algebra, &c.) A name given to the process by which any mathematical expression is changed into another of equivalent value or meaning, and of more expanded form. It is not to be understood that development either facilitates the calculation or the explanation of an expression, necessarily; it may sometimes do the one, and sometimes the other, but as often it is the reverse. Nevertheless, the mathematical use of an expression is frequently facilitated by employing its development, and this in a great variety of ways.

The expressions of common algebra will frequently furnish instances of this. Let us take the development of $(x+y)^3$, namely $x^3+3x^2y+3xy^2+y^3$. The original expression implies an addition and two multiplications, while the development involves six multiplications as difficult as those of the original, two of a more simple character, and three additions. Nevertheless the Binomial Theorem, of which the preceding is a particular case, is the foundation of many important branches of algebra. But the usual form of development is into infinite series [Series], a subject of peculiar interest, and the higher points of which, as may readily be seen from comparison of mathematical writings, are not perfectly well settled.

The mere word development suggests only one question, namely, what connection exists between the expression itself and its development. Are they both actual representations of the same arithmetical value? Or do they merely represent algebraical forms which have the same properties? There are cases in which the first question must be answered in the affirmative, and others in which the second question must be so answered, while it is palpably the contrary with regard to the first. Without entering into the reasons of such difficulties, it must here suffice to remind the student who seeks for such matter as is immediately connected with the common use of the word, that he must be cautious what he admits upon any point connected with it, since it may frequently happen that he will find himself endeavouring to reconcile a very narrow meaning of the term with the forms of expression used by writers who take for granted a knowledge such as can only be acquired by considerable experience and reflection. So wide is the modern use of the term, that the following caution may frequently be useful. When an author speaks of the development of an expression, remember that he may have so extended a signification of the word, that the student should consider him as meaning merely "algebraical substitute," or an expression which may be used for the original without change of algebraical properties. He will hardly understand what we mean, nor is it for our present purpose necessary that he should do so: our intention will be answered, if, in referring to this work for the use of this particular term, he should be distinctly made to understand that in all probability his difficulty arises from an indistinct view of the meaning of equality, or of the sign $=$, as employed in algebra, such as we conceive a very eminent modern English writer to have had, when he proposed, in order to overcome the difficulties attending the interpretation of a series, to consider *one plus one* as having a meaning distinct from *two*.

There are two points connected with developments which it may be worth while to point out, as illustrative of this (at first sight) apparent want of connection between an expression and its development, which it should seem ought to exist between two forms which are used indifferently each for the other.

1. An expression may preserve an algebraical identity with its development in cases where arithmetical identity is entirely lost. Let us consider the series $P = 1 + x + x^2 + \ldots$ continued without end, of which it is an evident property that $P = 1 + xP$. And the same is also a property of its well-known equivalent form $1 \div (1-x)$, which is in truth nothing more than the value of P derived from the last equation. But suppose that $x=2$, and there is no imaginable arithmetical connection between $1+3+4+8+\ldots$ continued for ever, and $1 \div 1(1-2)$ or -1. On this point, see Infinite, Divergent, and Series.

2. A development may present an intelligible result in cases where the original expression altogether loses meaning. Thus, let the following expression be considered: "the product of all whole numbers, beginning with 1 and ending with x," of which $1.2.3.4.5$, or 120, is a particular case. Considering this as a function of x, it is obvious that we can find meaning and value in all cases in which x is a whole number. But when x is a fraction, we lose all idea of meaning: what is implied, for instance, by the product of all whole numbers up to $10\frac{1}{4}$? Nevertheless, when we take the approximate expression for this product mentioned in Combinations, or the series of which it is the first term, namely,

$$\sqrt{2\pi x}\left(\frac{x}{\epsilon}\right)^x\left(1+\frac{1}{12x}+\frac{1}{288x^2}+\ldots\right)$$

the difficulty has disappeared: this series is as easily intelligible and calculable when x is a fraction as when x is a whole number. This paradox—namely, an alteration of form, giving more meaning to an expression than it had at first—is of a character which cannot be briefly treated.

The inverse word to development should be *involopment*; so that while we say that $1+x+x^2+\ldots$ is the development of $1 \div (1-x)$, we should also say that the latter is the *involopment* of the former. But the latter term is never used, which frequently gives rise to a circumlocutory and sometimes to a defective mode of description.

DEVICE, an emblem or ensign, formerly borne on shields or embroidered upon banners as a cognisance, contemporary, in the history of heraldry, with coat-armour itself. As early as the 12th century, King Henry II. caused certain devices to be painted, which had a descriptive reference to his name; the *planta-genista*, or broom-sprig, and a jenet passing between two broom plants, the former of which is engraved upon the great seal of his son, Richard I., on either side of the throne. For many succeeding centuries these devices appear to have been confined to the royal use; but from the reign of Richard II., various houses of the nobility adopted their use. Thomas Mowbray, duke of Norfolk, appeared against Henry, duke of Hereford, in the celebrated joust at Coventry, upon a horse whose velvet trappings were embroidered with lions and mulberry trees, intended to typify his name. The devices of greatest notoriety were the white and red roses, by which the contending families of the royal stem are still metaphorically described. From the close of the 15th to the middle of the 16th century the friezes, entablatures, and stained windows of the more sumptuous habitations were crowded with devices. The Bourchier and Stafford knots were of this description. Camden, in his Remains, has a section entitled 'Rebus, or Name-Devices;' these were probably adopted in imitation of the emblems which, during the Neapolitan wars of the 15th century, were painted by the Italian chiefs upon their shields, accompanied by mottoes or quotations descriptive of enterprise, or of the general character of the bearer. Such were called Impresses, from the Italian word 'Impresa.'

DEVISE. [Will.]

DEW is the moisture which, when the surface of the ground is colder than the atmosphere, whether at night or in the day, but principally, and as usually observed, between sunset and sunrise, is deposited from the air, in the form of minute globules, on the surface of bodies in contact with it. When the cold is extremely great, the vapour becomes solid instead of merely condensing into liquid water, forming a dendritic crystallisation of ice, or the globules of water freeze or solidify after deposition; producing what is called *hoar frost*, of two kinds.

The history of our knowledge of dew, as an object of scientific investigation, is singularly interesting, and the process by which it is formed involves several of the great principles of nature. In some remarkable speculations of Aristotle ('Meteor.' i. 10), it is supposed to be a species of rain formed in the lower atmosphere in consequence of the moisture which had been carried up during the day by evaporation being condensed by the cold of the night into minute drops. In 1784 Professor Patrick Wilson, of Glasgow, published a paper on hoar-frost in the Transactions of the Royal Society of Edinburgh, in which he supposes that cold is occasioned by its formation. In the course of the same year, and in 1788, Mr. Six communicated papers to the Royal Society of London in which he imagines that dew proceeds partly from the low temperature of the air through which the dew already formed in the atmosphere had descended, and partly from the evaporation of moisture from the ground, on which his thermometer had been placed. In a subsequent and posthumous work printed in 1794, the cold of the grass is, however, attributed, in agreement with the opinion of Mr. Wilson, altogether to the dew deposited upon it. Mr. Wilson and Mr. Six observed, that the production of (hoar-frost or) dew is accompanied with cold on the surface of the ground greater than in the atmosphere a few feet above, the differences being frequently 5, 10, or even more degrees of Fahrenheit's scale. This cold, as has just been mentioned, was considered as the effect of the formation of the dew, though this conclusion involved a very considerable difficulty; for as the transition of a body from the state of vapour to the fluid or solid form is always accompanied with an evolution of heat (which, as will appear in the sequel of this article, is really an element of the complex phenomenon under discussion), it might be expected that the surface on which the dew is deposited, and still more that on which the hoar frost is formed, would have its temperature raised, and no cause was apparent why it should be depressed.

Nearly contemporary with Six's last published observations, were some experiments made and described, though not explained, by M. Benedict Prevost, of Besançon. But Dr. Thomas Young, in his work entitled "Lectures on Natural Philosophy," published in 1807,—a mine of physical truth, which the labours of half a century have not exhausted,—completely accounted for the effects witnessed in those experiments, giving an explanation of them, of which it may be said, in accordance with a remark of his biographer the late Dr. Peacock, that it embraced the basis of the true theory of the cooling of the surface of the earth by radiation, and the interruption of that process by clouds, &c.—and by implication, that of the formation of dew itself. This, however, had remained unnoticed, and, indeed, until the discoveries of Leslie on radiant heat, but little further progress could be made in the investigation of this subject; and even the consequences of those discoveries remained for some time unperceived. But an obscure, because neglected, physician, giving his enforced leisure to physical inquiries, the late Dr. William Charles Wells, F.R.S., now discovered and established the true theory of dew, which Sir John F. W. Herschel ('Prel. Disc. on the Study of Nat. Phil.,' 168), has characterised "as one of the most beautiful specimens of inductive experimental inquiry," earnestly recommending the essay in which it is developed "for perusal to the student of natural philosophy, as a model with which he will do well to become familiar."

Dr. Wells, after verifying the facts previously observed, ascertained by numerous observations and experiments, that the cold at the surface, compared with that of the air above, precedes the formation of dew, and often exists without dew being formed; and that bodies become colder than the neighbouring air before they are dewed. The cold, therefore, which Mr. Wilson and Mr. Six supposed to be the effect of dew was found by Dr. Wells to be the cause of it.

The question, then, naturally arises, what are the causes which produce this low temperature of the earth, while the incumbent air is at a higher temperature? This is shown by the experiments and reasoning of Dr. Wells to be caused by the radiation of heat without an equivalent return. The surface of the ground allows a portion of the heat which it receives from the solar rays to escape by radiation when their action is withdrawn; hence its temperature falls; and if the air, holding watery vapour, rest upon it without much agitation (a circumstance by which, as the constant renewal of warm air imparts heat, the effect would be counteracted), a portion of the vapour will be condensed on the surface, and if the temperature is still lower, will be congealed: thus it is that dew and hoar-frost are formed only when the atmosphere is clear or the clouds not dense, for in the latter state they return an equivalent portion of radiant heat.

Dew forms in very different quantities on different substances under the same circumstances; thus, on metals it is sparingly deposited; on glass it forms abundantly, as it does also on straw, grass, cloth, paper, and other similar substances. Now as the metals radiate heat to a small amount only, and the other bodies mentioned in a much greater degree, they become consequently colder than the metals, and hence condense more vapour into dew.

Animal substances are among those which acquire dew in the greatest quantity; among these Dr. Wells found that swan's-down exhibited the greatest degree of cold in general, and was also most easily managed in experiment, as it was used while adhering to the skin of the bird. On other occasions wool was employed, and the following statements are the results of Dr. Wells's experiments with respect to the influence which several differences in the situation, mechanical state, and intrinsic nature of bodies have upon the production of dew.

A general fact is, that whatever diminishes the view of the sky, as seen from the exposed body, occasions the quantity of dew which is formed upon it to be less than would have occurred if the exposure to the sky had been complete; two parcels of wool, each weighing ten grains, were placed, one on the middle of a board, and the other to the middle of the underside; the two parcels were an inch asunder, and equally exposed to the action of the air: on weighing the two portions, it was always found that the upper portion had acquired most dew, the greatest difference being twenty grains to four grains.

The following is a tabular view of observations with respect to temperature made by Dr. Wells on the evening of the 19th of August, 1813:—

	6h. 45m.	7h.	7h. 20m.	7h. 40m.	8h. 45m.
Heat of air 4 feet above the grass	60½°	60½°	59°	58°	54°
,, wool on a raised board .	53½	54½	51½	48½	44½
,, swan's down on the same	54½	53	51	47½	42½
,, surface of the raised board	56	57	55½	..	..
,, grass plat . . .	53	51	49½	49	42

Sir Robert Barker and Mr. Williams have both given accounts of the process by which ice is formed in Bengal, while the temperature of the air is above 32°; and its production was attributed, by the former altogether, and by the latter in great measure, to cold produced by evaporation. Dr. Wells's experiments, however, show not only that the evaporation which occurs is insufficient to account for the effect, but that the cold produced by radiation alone will satisfactorily explain it. On the subject of such cold, Dr. Wells makes the following curious statement:—"I had often," he says, "in the pride of half knowledge, smiled at the means frequently employed by gardeners to protect tender plants from cold, as it appeared to me impossible that a thin mat, or any such flimsy substance, could prevent them from attaining the temperature of the atmosphere, by which alone I thought them liable to be injured. But, when I had learned that bodies on the surface of the earth become, during a still and serene night, colder than the atmosphere by radiating their heat to the heavens, I perceived immediately a just reason for the practice which I had before deemed useless." And he follows up this part of the subject by relating some extremely simple experiments in proof of the efficacy of the practice, and in explanation of the effect by the processes of the radiation and reflexion of heat.

It had been remarked by Aristotle * and by other writers that dew appears only on calm and serene nights. This observation, according to Dr. Wells, is not to be received in its strictest sense, as he has frequently found a small quantity of dew on grass, both on windy nights, if the sky was clear or nearly so, and on cloudy nights, if there was no wind. If, indeed, the clouds were high, and the weather calm, he has sometimes seen on grass, though the sky was entirely hidden, no very inconsiderable quantity of dew. Again, stillness of the atmosphere is so far from being necessary for the formation of this fluid, that its quantity has seemed to Dr. Wells to be increased by a very gentle motion in the air: but he says, "I can aver, after much experience, that I never knew dew to be abundant, except in serene weather," and "dew has never been seen by me on nights both cloudy and windy." †

Dr. Wells remarks that, during nights which are equally clear and calm, dew often appears in very unequal quantities, even after due allowance has been made for any difference in their lengths: thus it is more abundant shortly after rain than during a long season of dry weather. It is generally more abundant during southerly and westerly winds than those which blow from the north and the east; but this remark, of course, only applies to particular localities. To the greater or less quantity of moisture in the atmosphere, at the time of the action of the immediate cause of dew, are likewise to be referred several other facts respecting its copiousness; these are thus stated by Dr. Wells ('Essay,' p. 10):—

"In the first place, dew is commonly more plentiful in spring and autumn than in summer; the reason is, that a greater difference is generally found between the temperatures of the day and the night in the former seasons of the year than in the latter. In spring this circumstance is prevented often from having a considerable effect by the opposite influence of northerly and easterly winds; but during still and serene nights in autumn dew is almost always highly abundant.

"In the second place, dew is always very copious on those clear and calm nights which are followed by misty or foggy mornings: the turbidness of the air in the morning showing that it must have contained during the preceding night a considerable quantity of moisture.

"Thirdly, I have observed dew to be unusually plentiful on a clear morning which had succeeded a cloudy night. For the air having, in the course of the night, lost little or no moisture, was in the morning more charged with watery vapour than it would have been if the night had also been clear.

"Fourthly, heat of the atmosphere, if other circumstances are favourable, which, according to my experience, they seldom are in this country, occasions a great formation of dew. For, as the power of the air to retain watery vapour in a pellucid state increases considerably faster, while its temperature is rising, than in proportion to the heat acquired, a decrease of its heat, in any small given quantity, during the night, must bring it, if the temperature be high, much nearer to the point of repletion before it be acted upon by the immediate cause of dew, than if the temperature were low. * * * * *

"In the last place, I always found, when the clearness and stillness of the atmosphere were the same, that more dew was formed between midnight and sunrise than between sunset and midnight, though the positive quantity of moisture in the air must have been less in the former than in the latter time, in consequence of a previous precipitation of part of it. The reason, no doubt, is the cold of the atmosphere being greater in the latter than in the prior part of the night."

The experiments of Dr. Wells were repeated in France by M. Pouillet; but two sets of experiments of some value, undertaken for special purposes by the late Professor J. F. Daniell, appear to have

---

† 'An Essay on Dew, and on several appearances connected with it,' Lond. 1814, p. 65. It may be well to record, as the late Dr. T. Thomson pointed out at the time, that the word *conduction*, as applied to a certain process of the propagation of heat (and subsequently to that of electricity) was first introduced into the English language by Dr. Wells in this work. A second edition of the Essay appeared in 1818, which was republished shortly after the author's death, in a now scarce volume, containing other writings by him, including his autobiography, Lond. and Edin. 1818, 8vo, reissued in 1820.

been the only attempts made in England to confirm and extend the results at which Dr. Wells had arrived, until after the establishment of the magnetical and meteorological department of the Royal Observatory at Greenwich, when Mr. James Glaisher, F.R.S., the superintendent (as an assistant of the astronomer royal) of that department, instituted, carried on for some years, and afterwards communicated to the Royal Society, an elaborate and most valuable series of observations and experiments "On the amount of the Radiation of Heat, at night, from the earth, and from various bodies placed on or near the surface of the earth." These were published in the 'Philosophical Transactions' for 1847, of which they occupy 113 pages, including 108 tables of observations. The subject of the production of dew was, of course, only a part of Mr. Glaisher's researches; but the most general result he obtained on that subject, was entirely conformable with that enunciated by Dr. Wells, and is stated in the following terms:—

"The formation of dew was found to depend solely on the temperature of the bodies upon which it was deposited, and it never appeared upon them till their temperatures had descended below that of the dew-point in their locality, as found by observations of a dry and wet bulb thermometer placed in their vicinity. The amount of water thus deposited was the greatest upon the substances whose temperatures were the lowest." The *dew-point*, as will be explained in the next article, is the critical temperature below which the vapour of the atmosphere begins to be condensed into moisture, the "point of repletion" of Dr. Wells, as above.

At the commencement of his experiments Mr. Glaisher made some precise and important observations, on the difference between the temperature of a thermometer and that of a body in contact with it, which must here be noticed, on account of the bearing which they have on the conduct of experimental inquiries of this nature. Among the bodies found to radiate heat freely (in agreement with previous knowledge), was glass, which thus very readily became wet with dew. In consequence of this property, the tube of a naked thermometer, which was lying on a substance entirely free from moisture, was frequently found covered with dew, and therefore it seemed probable that the temperature exhibited by the instrument was not that of the body in question. On such instances occurring an attempt was made by Mr. Glaisher to correct the error, by enclosing the thermometer stem in a tube made of gilt paper; the bulb alone, resting on the substance, remained exposed to the sky. The differences between the readings of a thermometer thus enclosed, and when naked, were found to be sensible, but small in amount; it was also observed, that when the thermometer was wholly naked the stem was at times wet when the bulb itself was dry; and at all times much less moisture appeared on the bulb than on the stem, unless the disposition of the substance in question to become cold was the same with, or greater than, that of the glass. The error arising from this cause was chiefly confined to the consequent contraction of the mercury in the stem, and not in the bulb, and which was considered to be avoided by the use of gilt paper. The error in all cases must have been small. Mr. Glaisher found, in addition, that one of the many sources from which the reading of a thermometer placed on the ground is affected, is the heat evolved during the change of the watery vapour in the atmosphere into dew, the amount of which appeared to be about 4° Fahr. from all the experiments he made. The difficulty this fact occasioned to some of the earlier theorists on dew has been noticed above.

It was found, in the course of these experiments, that the differences between the temperature of the air and of bodies on the earth, at night, in equally calm and clear weather, were the same at every period of the year, but it was also found that the amount of dew deposited during such times was much greater in summer than in winter. This is easily accounted for, from the well-known relation existing between temperature and moisture. At all seasons of the year, at night, the depression of the temperature of the dew-point below that of the air is small, or the air is in a state of saturation nearly, and therefore in summer a certain diminution of temperature would cause much more vapour to be changed into water, than an equal diminution in winter would do; in agreement with the previous reasoning of Dr. Wells.

With respect to the occasional formation of dew in the day-time, Mr. Glaisher remarks, "Radiation of heat from the earth to the heavens must exist at all times, both day and night, and in all states of the sky. Generally, when the sun is above the horizon, the heat emitted by it to the earth will overbalance that which the earth radiates upwards; at times, however, in places shaded from its direct beams, the amount of heat radiated exceeds that received from the sun and all other sources, and dew will be continually deposited throughout the day." Some instances of this are exhibited in his Tables. Dr. Joseph D. Hooker, we may add (in his 'Himalayan Journals,' vol. i., p. 198), has recorded, in conformity with this principle, that in East Nepaul, the sun, in many places, does not reach the bottom of the valleys until 10 A.M., and is off again by 3 P.M.; and that the radiation to a clear sky is so powerful that dew frequently forms in the shade throughout the day. But in these regions the clearness of the sky is such, that at night Dr. Hooker found the upper blanket of his bed to become coated with moisture, from the rapid abstraction of heat by the tarpaulin of his tent, itself frozen by its own radiation.

From some of Mr. Glaisher's tables, containing the results of observations when the excess of air-temperature above that of long grass amounted to 5°, 6°, 7°, or 8°, it appears that at such times the sky was frequently cloudy, and when wholly so, that the clouds were high; that the air was in frequent motion, and at times the wind was blowing with a pressure of 4 lbs. on the square foot; that the atmosphere was occasionally thick by haze or vapour, and that under these circumstances, dew was seldom deposited. Other tables contain the results of the observations when the excess was 9°, 11°, or 12°, and at those times the sky was generally clear, the air calm, and the atmosphere frequently hazy or misty, or vapour or fog was prevalent, and dew was also frequently deposited; in two cases, one in February and the other in November, the sky was wholly covered by high and thin clouds, the radiation of heat from which was thus inadequate to counteract that of the earth, as had been before observed by Dr. Wells.

It was also observed by Mr. Glaisher, that the various amounts of dew deposited, at the same time, on different bodies at night, were, as near as could be determined, proportional to the amount of the depression of their temperature below that of the dew-point. "Hence, it is evident," he concludes, "that all hygrometers formed of any of these substances [a variety of bodies in common use, chiefly belonging to the mineral kingdom, as chalk and graphite, but including the common metals also], or of any animal or vegetable substance, when exposed to the clear sky at night, will be cooled by the radiation of their heat, and will cool the air in contact with them; and thus indicate a greater degree of humidity than actually exists (as had been pointed out by Dr. Wells, with respect to the organic substances); and particularly so, should their temperature descend below that of the dew-point, and dew be actually deposited upon them."

Contemporary, as it would appear, with the researches of Mr. Glaisher, and equally elaborate and satisfactory, were those of the lamented Italian philosopher Melloni, who had made almost the entire subject of radiant heat emphatically his own. They were read to the Royal Academy of Sciences of Naples, very shortly after Mr. Glaisher's paper was read before the Royal Society of London; seem to have been undertaken, in part, on account of the obstinate and perhaps traditionary retention in certain Italian schools of science of the ancient notions on the formation of dew; and are throughout, in the most remarkable manner, confirmatory of the discovery of Dr. Wells, while they correct some of the tacit admissions of his theory and elucidate others. They are also, in a great degree, comparable in detail with those of Mr. Glaisher, with which they present an accordance, that when characterising the labours of two physicists accurately versed in their subject, is itself strong evidence of the truth. But M. Melloni adds to the causes of complication in the actual phenomena of dew, as investigated by the English meteorologist and his predecessors, that of the great emissive or radiant power of water, which has important bearings on every part of the series of phenomena, after the first actual deposition of dew, and in all probability is the reason why the thermometer wetted with dew, described by Mr. Glaisher as above, did not introduce any serious error into his observations.

A great part of Melloni's three memoirs is devoted to the experimental verification of the proposition that almost all the facts which precede and accompany the formation of dew result from the presence, of shorter or longer duration, of the air around the radiating surfaces. He investigates with great success the circulation of temperature, and of local amount of vapour in the different atmospheric strata adjacent to the earth's surface, under the influence of nocturnal radiation. For the results, however, as well as for a discussion of the geographical distribution of the varying phenomena of dew, we must refer to the author's original memoirs 'On the nocturnal cooling of bodies exposed to a free atmosphere in calm and serene weather, and on the resulting phenomena near the Earth's surface,' 'Ann. de Chim. et de Phys.,' Feb. and April, 1848; or (Taylor's) 'Scientific Memoirs,' vol. v., pp. 453-476, 530-552. [CLOUD, HOAR-FROST, HYGROMETRY, METEOROLOGY, RADIATION OF HEAT, RAIN, VAPOUR.]

DEW-POINT. The critical temperature, usually expressed in thermometrical degrees, of the double atmosphere of air and aqueous vapour (or of any portion of the earth's atmosphere in its natural state), below which the latter becomes condensed into liquid water, and above which that atmosphere will convert into vapour and absorb into itself (augmenting the quantity of the vapour) water with which it may be in contact. In the former case the water becomes condensed into minute globules like those of the clouds, which, if the condensation take place against solid surfaces of lower temperature, become attached to those surfaces in the form of dew; hence the origin of the term.

Viewing the same subject in a slightly different aspect, Sir John Herschel defines the dew-point as "the temperature which the air ought to have, so as to be exactly saturated with the quantity of vapour it actually contains."

The phrase *depression of the dew-point* denotes the quantity of heat to be abstracted, or the number of degrees of the thermometer below the actual temperature of the atmosphere which it requires to be cooled, in order that the vapour it contains may become so condensed.

The following examples will illustrate the use of these expressions. In the Greenwich Meteorological Observations for 1857 it is recorded that, on July 15, the mean daily reading of the thermometer, or the air-temperature, was 72°·7 Fahr., and that of the dew-point 58°·2, the difference of which, 14°·2, is the depression of the dew-point; and that on December 15, the air-temperature was 46°·9, and that of the dew-point 44°·8, the depression consequently, 2°·1.

The mean air temperature for the same year was 51°·0, and that of the dew-point 45°·8; the depression 5°·2, which is slightly below the average of the climate.

In the Sikkim Himalaya, according to Dr. J. D. Hooker, the dew-point, on the average of the year, is 49°·3, or 3° below the mean temperature of the air. In the dampest month (July) the mean dew point is only eight-tenths of a degree below the mean air-temperature, whilst in December it sinks 10° below it.

Professor C. Piazzi Smyth found that no dew was formed on the Peak of Teneriffe, at his astronomical observing stations. "In a region," he says, "where the average depression of the dew-point was, as we found it, the unheard-of quantity of 40°, and where it was not unfrequently above 50°, the formation of dew was physically impossible." ('Phil. Trans.' 1858, p. 478.)

The determination of the dew-point and of its depression being as it were the *index* of all hygrometry, a variety of methods and processes have been devised, and instruments constructed for the purpose, or virtually so, from the era of the Academicians del Cimento to that of Dalton, and from his time to the present. This long and varied experience has resulted in the almost universal adoption of a method at once simple and satisfactory—the simultaneous observation of the dry-bulb and the wet-bulb thermometers, an explanation of which will be given in the article HYGROMETRY. The use of Daniell's hygrometer, however, for this purpose, is continued by some meteorologists.

The *Vapour-Plane* in the atmosphere, on which the clouds float, is the superior limit of a stratum which is at the temperature of the dew-point, at and below which cloud is continually forming, while it is as continually being resolved into invisible vapour above. [CLOUD, METEOROLOGY, VAPOUR, VAPOUR-PLANE.]

DEXTRINE ($C_{12}H_{10}O_{10}$). An isomeric modification of starch procured by boiling common starch in dilute sulphuric acid, and also in some other acids; by this treatment the starch soon loses its consistence and becomes thin and limpid, being converted into *dextrine*, so called from its action on polarised light, in causing the plane of polarisation to deviate to the right. When sulphuric acid is used, it is to be saturated by the addition of chalk, and the liquor, filtered from the sulphate of lime formed, is to be evaporated to dryness in a water-bath.

Dextrine thus obtained is a white gum-like mass, without any appearance of crystallisation, soluble in cold water, and precipitable from it by alcohol. Iodine is stated by some authors sometimes to produce no change in the solution of dextrine, and on other occasions to give a purplish red tint. The non-production of colour has, however, been stated to be a test of the perfect conversion of the starch.

Dextrine may also be prepared by the action of an infusion of malt kept some time at 150°. Its composition is similar to that of starch.

When the heat is continued after the formation of the dextrine, this substance is converted into grape sugar, and this effect is produced with great readiness.

Dextrine, but not quite pure, is used by calico-printers as a substitute for gum; it is obtained by merely subjecting starch to the action of heat, and thus prepared is known by the name of British gum. [BRITISH GUM.]

DEXTRO-RACEMIC ACID. [TARTARIC ACID.]

DEY. The origin of the word dey is uncertain. Some have derived it from the Turkish *dâi*, "a maternal uncle," and have supposed that this designation was given to the chiefs of the states of Barbary to express their almost paternal authority in the Ottoman empire, and the high esteem in which they were held by the Porte. The name is at all events of more ancient date than the Ottoman dominion in northern Africa, since we find it used as early as the end of the 11th century as the title of the emissaries of the Assassins or Ismaelites. The dignity of dey, or bey, of Tunis, Tripoli, and Algiers, was borne by the governors who were tributaries to the Turkish empire. Algiers is now in the possession of the French, Tripoli is a pashalic of the Turkish empire, and in Tunis alone does the title exist, though it more frequently appears as pasha-bey. [ALGERIE, L'; TRIPOLI; TUNIS; in GEOG. DIV.]

DIABETES, the discharge of a preternatural quantity of urine, the chemical composition of which is also essentially changed. In this disease the urine is not only unusually large in quantity, but it is either altogether destitute of several of its constituent principles, or it contains them only in very minute proportions, while it acquires a new ingredient, a quantity of sugar, which imparts to it a sweet taste. Medical writers are not agreed whether the impregnation of the urine with a sufficient quantity of saccharine matter to render it sweet to the taste be absolutely essential to the disease; it is therefore usually divided into two species, namely, *diabetes insipidus*, when there is discharged a preternatural quantity of urine which is perfectly insipid, and *diabetes mellitus*, when the unusual quantity of urine which is voided is sweet to the taste.

The discharge of a larger quantity of urine than natural, unaltered in its chemical constitution, may arise from numerous causes of a temporary nature, scarcely deserving the name of a disease, and certainly not forming a disease of a specific character. The term diabetes should therefore be restricted to that specific disease in which the secretion of urine is preternaturally increased, and its chemical composition at the same time essentially changed.

In diabetes, properly so called, the urine is generally so clear that it appears at first sight to be entirely without colour; but viewed in a certain light, it is seen to be slightly tinged with a yellowish green, or it is of a pale straw colour. Examined by the taste, it is almost invariably found to be more or less sweet; and when chemically analysed, it is ascertained to contain, usually in considerable quantity, a saccharine matter, which has many of the properties of common sugar. Its odour is likewise peculiar; it is commonly compared to the faint odour of violets, or to that of sweet whey or milk. Its specific gravity commonly varies from 1·025 to 1·052. From a table given by Dr. Henry, it appears that ten pounds of diabetic urine, at the average specific gravity of 1·040, yields upwards of a pound and a quarter of solid extract.

The quantity of urine voided in this disease is sometimes enormous. In one case on record, it amounted to the prodigious quantity of 52 pounds in the 24 hours; but instances are by no means uncommon in which the quantity amounts to from 25 to 35 pounds every 24 hours for weeks or even months together. Although one of the most constant constitutional symptoms attendant on this disease is inordinate thirst, yet the urine daily voided almost always exceeds the quantity of liquids drank, and sometimes the whole of both solids and liquids.

The diabetes commonly comes on slowly and almost imperceptibly, at least without any such disorder of the general health as to attract particular notice. It therefore sometimes exists a considerable time before it becomes known; and the change in the quality of the urine is at length discovered by accident; for its quantity may not at first be very much increased, or if increased to such a degree as to attract notice, the circumstance is usually attributed to some temporary cause. At length, however, the constitution manifestly suffers; the strength and vigour fail, the patient feels languid and indisposed to make any physical exertion, the mouth is dry, the tongue clammy; there is unusual thirst; a slight degree of fever is set up, indicated by alternate chills and heats; but the most remarkable circumstance is a change in the condition of the skin, which becomes dry, harsh, and sometimes even furfuraceous, or apt to peel off in scales. The thirst now increases to such a degree as to be evidently morbid; this is often, though not always, accompanied with voracious appetite; and the quantity of urine discharged not only decidedly but steadily increases. If the observation of these circumstances should lead to the examination of the urine, it is found to be sweet to the taste and of a light green or pale yellow colour. The patient meantime is commonly observed to have lost flesh, and is troubled with a sense of heat and pain in the region of the stomach, with aching in the back and loins, and uneasy sensations in the course of the urinary passages. The bowels are usually costive, the breathing short and oppressed, with a dry tickling cough, and the pulse is commonly frequent. As the disease advances, all these symptoms increase in intensity; the tongue becomes either loaded with a dark-coloured fur, or unnaturally clean and of a dark or purplish red colour; the thirst is more urgent; the appetite, formerly voracious, is now perhaps abolished or depraved; the bowels are more constipated; the skin more harsh and scaly; while the urine, increasing in quantity, becomes still more altered in quality. At length there come on headache, giddiness, occasional loss of vision, impaired memory, and diminished mental energy. The debility and emaciation steadily increasing, the patient sinks with many of the symptoms of hectic fever, or is suddenly cut off by consumption, dropsy, apoplexy, or some other incurable disease established in some vital organ.

From the preceding account it appears that this disease is generally of a chronic character; but it sometimes attacks in an acute form, the marked symptoms of the malady coming on suddenly in a previous state of apparent health, and proving fatal in a few days. This, however, is very rare. It seldom runs its course under some months, and it sometimes lasts several years. It frequently disappears for a while, especially under proper treatment, and then recurs after the lapse of a few months or years; so that the relief obtained is commonly only temporary, the disease resuming all its severity from a slight exposure to its exciting causes, or from any considerable deviation from the proper diet and regimen. Hence it is perhaps the prevalent opinion among physicians that it is absolutely incurable. There cannot be a question that by appropriate remedies and great and persevering care on the part of the patient, it is capable of being very much relieved, and even of being altogether suspended for an indefinite number of years. The evidence of this is indubitable; but it is more doubtful whether it can be permanently and radically cured.

An inspection of the organs after death does not throw so much light on the seat and nature of diabetes as might have been expected. In several cases in which the symptoms were present in a very intense degree during life, no appearance of change of structure in the urinary organs could be detected after death. In general, however, the kidneys are larger than natural; more turgid with blood; more flaccid; softer, and more easily torn. Sometimes, though rarely, they are found in the contrary condition, smaller and harder than natural, and their membranous envelope and their cortical substance, are of a cartilaginous firmness and density. Several observers have recorded the remarkable fact, that the organic nerves which supply the kidneys are greatly enlarged in size. The ureters are commonly dilated, and the urinary bladder is often thickened. It is obvious that these mordid states of the kidneys may be the effects of the disease, and not the causes of it. Next to the kidneys, the organs most commonly found in a state of disease are the mesenteric glands, which are enlarged and hardened. The absorbent glands in general are occasionally enlarged, softened, and more vascular than natural; the thoracic duct is sometimes dilated, and the lungs are constantly found studded with tubercles in all their stages of disease. Though the functions of the stomach, intestines, and liver are so often disordered during life, yet it is comparatively rare that any kind or degree of organic change is discoverable in these organs after death.

The true and invariable antecedents of diabetes, or its proper exciting causes, are still involved in obscurity. It has been observed to come on after exposure to several morbid agents, as the long-continued application of cold and moisture, especially after the body had been previously over-heated, implying a sudden check to the perspiration, and a corresponding determination of blood from the skin to the internal organs; exhaustion arising from excessive evacuations, or excessive fatigue, bodily or mental; in short, whatever greatly and suddenly depresses the powers of life: but such causes are applied in all their intensity to the human body many thousands of times for one in which they produce a case of diabetes.

Although morbid anatomy throws so little light on the nature of this disease, the recent discovery of sugar in the blood affords grounds for supposing that the real seat of this disease is in the blood, or the organs concerned in the production of the constituents of the blood, rather than in the kidneys. Sugar is not, however, found in all blood, but was first found in the hepatic vein, and was found to be absent in the portal vein. This discovery was followed by researches on the function of the liver, more particularly by M. Bernhard, of Paris, who was the first to announce the fact that the liver had the power of converting the constituents of the blood in the portal vein into sugar. The sugar found in the liver more closely resembles in its properties, glucose or grape-sugar, than cane-sugar. It is this sugar apparently that increases in the blood during the disease called diabetes, and this is confirmed by the fact that there is a close resemblance between diabetic- and liver-sugar.

As in the diagnosis of diabetes it becomes a matter of importance to detect the presence of sugar in the urine in the earliest stages, much importance has been attached to the means of discovering small quantities of sugar in the urine. The tests used are numerous, but it may be sufficient to mention here those which are most conveniently applied.

The first we may mention is a colour test, and is known as Moore's test. It consists of adding the *liquor potassæ* to the suspected urine in a test-glass and then exposing to the heat of a spirit-lamp; if sugar is present, the urine becomes changed into a bright claret colour. Of course the intensity of the colour will depend on the quantity of the sugar. Dr. Garrod has proposed a modification of this test in his glucometer, which by supplying a standard solution enables the experimenter to judge of the quantity of sugar present by the quantity of liquor potassæ required to produce the standard colour.

Another test more frequently used is that of Trommer. This depends on the facility with which diabetic sugar is decomposed in contact with an oxide of copper. A solution of sulphate of copper is added in a test-tube to the urine, sufficient to colour it blue. Liquor potassæ is then added, which throws down a hydrated oxide of copper. On exposure to heat the sugar is decomposed, and the oxide of copper is reduced to the state of a suboxide, which is known by its red colour. This test is equally efficient for grape-sugar and liver-sugar, but the above changes go on very slowly in cane-sugar.

Crystals of sugar may be detected in the urine after evaporation, under the microscope, and the process of fermentation may be established by the addition of yeast. These are other tests, but not so much to be depended on as the preceding.

Various theories have been proposed to account for the sugar in the urine, and a treatment has been recommended in accordance with such theories. Dr. Prout attributed the disease to a deranged state of the digestive organs, in which he believed the food was converted into sugar in the stomach and intestines, and thence carried into the blood.

Dr. Bence Jones has explained the occurrence of the sugar, on the ground that in health the natural changes of certain portions of the food are from starch to dextrine, from dextrine to sugar, and from sugar to carbonic acid. But in diabetes the last stage of change is arrested, and the sugar not being converted into carbonic acid is carried off from the blood by the kidneys.

M. Bernhard, as the result of his researches on the sugar-forming properties of the liver, regards diabetes either as the result of a too active performance of the function of sugar-forming in the liver, or as produced by a deficient decomposition of the sugar naturally thrown into the blood.

The treatment suggested by these theories is not inconsistent with the mode of treatment employed by the older practitioners of medicine. It was early suggested that those kinds of food which contained substances that were easily converted into sugar, and sugar itself should be withheld, and many patients were found to improve greatly, and even to get well, by withholding substances containing starch and sugar from their diet. In some cases this plan has been pushed to the extent of giving the patient nothing but animal food. This, however, is so repugnant to the natural taste of the patient that most practitioners have allowed a limited quantity of bread, or prescribed a kind of bread in which the gluten is in much larger quantities than usual. Such bread has been manufactured for the use of diabetic patients. It cannot be said, however, that such bread is necessary to the cure of diabetic patients, as many have improved on a diet in which animal matter has constituted a principal part of the diet, combining this with a small proportion of the farinaceous vegetables.

The most curious point in the history of this disease is, that cases have been recently published by Dr. Budd, of Bristol, and others, in which they have administered large quantities of sugar to diabetic patients with decided advantage to the patient. Although there can be no doubt of the improvement thus recorded, abundance of cases exist which show that the free administration of amylaceous and saccharine foods has been attended with an increase of the diabetic symptoms, and that relapses have been frequent after improvement on an animal diet, by the partaking of fruits and farinaceous foods.

These facts lead to the conclusion that diet alone will not cure diabetes. Nor are there any special remedies that will effect a cure. But the treatment should be directed to the restoration of that state of the system in which only the normal quantity of sugar is allowed to remain in the blood. Under these circumstances the digestive system, the liver, and the blood, should, if possible, be restored to their natural condition. This may be done by the administration of purgatives where needed, by giving tonics such as iron and quinine, which restore the tone of the system, and especially in the administration of medicines which act on the nervous system. There is reason to believe that deranged conditions of the nervous system alone will cause the appearance of sugar in the urine quite short of ordinary diabetic symptoms, and there is abundant evidence to show that opium, camphor, kreasote, and remedies of this class will frequently control the quantity of sugar in the urine.

An important element in the treatment of these cases is abundant exposure to fresh air. Horse exercise, or walking where it can be borne, should be recommended. This should be done on the principle of securing the greatest possible amount of oxidation for the constituents of the blood, as there can be no doubt that one element of the disease consists in deficient change in the blood.

The state of the skin also demands attention. Warm bathing and the vapour-bath have proved beneficial, and daily ablution of the whole body in warm and cold water, according to circumstances, should be prescribed. Warm flannel clothing should also be worn next the skin.

DIABETIC SUGAR. [GRAPE SUGAR.]

DIACAUSTIC CURVE. [CAUSTICS.]

DIAGONAL, a line drawn from corner to corner; any line drawn from point to point of a figure, which is not part of its boundary, provided the two extreme points be in the intersection of boundary lines. A figure of n sides has $\frac{1}{2}n(n-3)$ diagonals.

DIAGONAL SCALE. Equidistant parallel lines cut *all* lines drawn across them into equal parts. Consequently, a set of equidistant parallels laid down upon a ruler, with oblique lines of various lengths drawn across them, give, with the compasses, the means of immediately taking off various proportions of those lines. But the common diagonal scale is as follows, and facilitates the laying down of the hundredths of units in a scale of equal parts. A description of its use will immediately suggest the principle of it to any one slightly acquainted with geometry. A B is the unit of the scale (usually a quarter of an inch): the diagonal scale professes to determine the hundredth part of this, or the four-hundredth of an inch, and may perhaps, with care, be depended on within the two-hundredth of an inch. By taking off various lines, and writing their numerical designations opposite, we may show the use and meaning of the construction.

DIAGRAM, a mathematical figure of any kind.

DIAL, an instrument for determining the hour of the day from the shadow of a point or line upon a graduated surface. The shadow may be that formed by the light of the sun or moon, and be either direct or reflected. The dial, when the sun is used, is called a sun-dial; and when the moon, a moon-dial. The latter kind, as well as those in which the light is reflected, are mere objects of scientific curiosity, and no further notice will be given of them in this work; but the history and structure of the sun-dial will be found under SUN-DIAL.

DIALECT (διάλεκτος, δια-λέγ-εσθαι, *to converse*), an appellation given to a language when spoken of in contradistinction to some other language which it resembles in its general features, though differing from it more or less in the details. Almost all the languages which we are acquainted with may be arranged in distinct classes or families, and the relationship subsisting between the members is, generally speaking, pretty obvious. Sometimes the parent language from which they are all descended is still extant, and in that case it is frequently easy to trace the variations in orthography, inflexion, and conjugation from the parent stock, and to determine the principles which governed these changes. These inquiries, whenever they can be successfully prosecuted, are of the greatest importance, as well to the critical historian as to the philologer; for the language of a people points at once to their mental characteristics and the external changes to which they have from time to time been exposed. Thus the Dorian dialect of the Greek language, in the broadness and harshness of its vowel sounds, corresponds to the grave and austere character of the Dorian people; and whenever a warlike race has taken up its abode among a peaceful agricultural population, traces of this mixture of population are always found in the language, in which the military and political terms are mostly peculiar to the language of the conquerors, while for the words referring to farming and domestic economy, the aboriginal language is retained. This is strikingly the case in the Latin and English languages. The two most widely diffused families of languages known to us are the Indian-Gothic and the Semitic; the former includes the Sanscrit, Zend, Armenian, Greek, Latin, Lithuanian, Sclavonian, Teutonic, and Celtic dialects, in which the resemblances, though sometimes rather distant, are still more or less perceptible. The Semitic family contains the Hebrew, Syriac, and Arabic tongues, with others less known to modern Orientalists. Many of these primary dialects are divided into several sub-dialects: for instance, the ancient Greek had at least three distinct dialects, the Æolian, Dorian, and Ionian.

The differences in the modes of speaking in England can hardly be called dialectical, in the sense in which the word dialect has been explained: such differences, generally speaking, are nothing more than peculiar words or phrases which the written language has not adopted, but which are not the less on that account genuine members of that Teutonic family of which the written language itself is only a part.

But so far as any of these varieties have been committed to writing, and are admitted by a large portion of the population to be a faithful representation of the language in daily use among them, so far such varieties may not inaptly be called dialects. Such are many of the poems of Burns, and parts of the novels of Scott. In ordinary conversation in England, the words "provincialism" and "dialect" are often used as synonymous, and as expressing some usage of language which is at variance with the established language of the educated and that of the best writers. It is, however, only a vulgar mistake to consider such words as "corruptions" of language, which they very rarely are. As a general rule, such words and phrases, and such peculiar pronunciations as characterise nearly every county of England, are of the genuine Teutonic stock; and that language which is now the established language of literature, and which has rejected some of the so-called provincialisms and adopted others, might, under different political circumstances, have contained these elements in a different proportion. If the metropolis of England had been on the Severn, the Humber, or the Tyne, who can say how much the written language might have been affected by this circumstance?

DIALECTICS (διαλεκτική τέχνη), the old name for the practical part of logic. The word properly signifies "the art of conversation," and its use as a name for the art of reasoning seems to have arisen from the fact, that Zeno the Eleatic, who was the first compiler of a system of logic, was also the first writer of dialogues. It is also to be remembered, that formal argumentation among the Greeks was generally carried on by means of question and answer, and Aristophanes uses the more common word *dialexis* (διάλεξις), to signify the logic of the Sophists. There were several systems of logic between Zeno and Plato, as, for instance, those of Protagoras, Polus, Gorgias, Euclid, and Eubulides. Socrates never committed any thing to writing; but if we take the representations given of his mode of reasoning by Plato and Xenophon, so far as they agree, we must look upon him as in some measure the originator of Plato's scientific method of arguing. (See Schleiermacher on the Worth of Socrates as a Philosopher, in the Transact. of the Berlin Acad. for 1815, transl. in the Philolog. Mus. vol. ii.) Plato considered dialectics as the science of definitions ('Sophist.' 253), and as every definition must include both genus and difference, he found it necessary to invent a theory of abstract ideas as the basis of his dialectics; for the ideas (ἰδέαι) and the genera (εἴδη) were, he considered, related merely as subject and object; and he thought that, without assuming the objective existence of the genera, he could have no real general ideas, and so his definition, and consequently his whole dialectical system, which he believed to be the only available means of finding out the truth, would fall to the ground. (Van Heusde, 'Initia Philosoph. Platon.;' Cousin, 'Fragmens.') Aristotle's dialectics were based upon a scale of categories or predications, much the same with those of Archytas; he did not think it necessary to assume any *à priori* abstract notions, but conceived it was sufficient for all logical purposes to generalise after experience. (Facciolati's 'Logica Peripatetica.') The dialectics of the Stoics appear to have been little more than a system of grammatical rules. For the application of dialectics the reader is referred to the article LOGIC; and to the works on the subject by Sir W. Hamilton, A. De Morgan, W. Spalding, and others.

DIALLYLUREA. [UREA.]

DIALURAMIDE. [URIC ACID.]

DIALURIC ACID. [URIC ACID.]

DIAMAGNETISM. There are certain bodies which are attracted indifferently by either magnetic pole, and are termed *magnetic;* but there are others which, when brought near to the magnetic pole, are repelled instead of being attracted; such bodies are called *diamagnetics*, and the branch of science which treats of them is termed *Diamagnetism*. [MAGNETISM.]

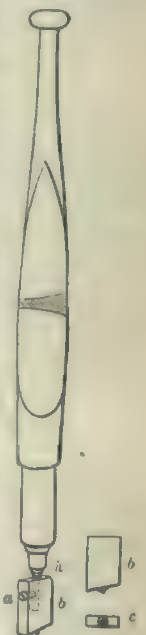
DIAMETER, a word most commonly applied to the line drawn through the centre of a circle, and bounded on both sides by the circumference. But the most general meaning is as follows:—Whenever any point is called a centre, any line drawn through the centre is called a diameter. And any point which bisects all lines drawn through it from opposite boundaries is called a centre. Thus the circle, the conic sections, the parallelogram, the sphere, cube, and parallelopiped, all have *centres*, and by analogy, *diameters*.

DIAMIDES. [AMIDES.]

DIAMIDO-BENZOIC ACID ($C_{14}H_5(H_2N)_2O_3,HO$). A derivative by reduction from *binitrobenzoic acid*. [BENZOIC ACID.]

DIAMINES. [ORGANIC BASES.]

DIAMOND. The pencil diamond used by glaziers in cutting glass is a small fractured piece of the gem. The part of the diamond used for cutting is of a trapezoidal shape, weighing about the 60th part of a carat, and is set in a wooden handle, which consists of a rounded piece of rose-wood flattened at the two sides to fit between the sides of the fore and middle fingers.



Two kinds of pencil diamonds are in use. The old diamond is merely set fast in a conical shoulder. A difficulty is always experienced in cutting glass with this sort of pencil, owing to the uncertainty of placing the gem at once at the proper angle with the glass, so as to make it cut and not scratch; this difference depends upon the axis and edges of the crystal. The patent diamond, of later invention, overcomes this difficulty. The form is represented in the annexed figure. The peculiarity consists in the diamond being set in a parallelopiped shoulder, *b*, *b*, the right angle of the lower end of which is cut off and forms the correct angle at which the diamond when set will cut the glass. The upper end of the shoulder swivels at *h*, but is stopped from going too far by the screw *a*. The object of this is to prevent the necessity of shifting the handle in the hand when placed against the ruler laid on the glass. The lower end of the shoulder, showing the diamond, is represented at *c*. A large diamond is not so fit for the purpose of cutting glass as a small one. The diamond is usually about the size of an ordinary pin's head, and is set in a nipple of brass or copper. It is an error to suppose that diamonds will not wear out. In the shops of wholesale glaziers, where the diamond is in constant requisition, one of these instruments is worn down in a month or six weeks, so as to require resetting, after which, with the same wear, it usually lasts another month, and then becomes useless. It may be presumed that they travel over some miles of glass before they are worn out. In cutting the glass, care is taken not to press too heavily on the diamond, which is apt to scratch instead of cutting the glass; such heavy pressure also spoils the diamond.

The cutting of glass may also be effected by unusually hard specimens of certain other minerals; but the diamond is the only means regularly employed.

DIAMOND. [CARBON.]

DIAMYLAMINE. [AMYL.]

DIAMYLANILINE $\left(N\begin{cases}C_{12}H_5\\C_{10}H_{11}\\C_{10}H_{11}\end{cases}\right)$. An organic base derived from *aniline* by the substitution of two equivalents of amyl ($C_{10}H_{11}$) for two of hydrogen.

DIAMYL-OXAMIDE. [OXAMIDE.]

DIANA. [ARTEMIS.]

DIANILIDES. [ANILIDES.]

DIAPA'SON, in Music (διὰ, *through*, and πασῶν, *of all*), the interval of the octave, so called because it includes all admitted musical sounds. It likwise signifies the compass of any voice or instrument; and the French employ it to express what in England is meant by the term *concert-pitch*. [CONCERT-PITCH; TUNING.]

DIAPASON STOP, in an organ. [ORGAN.]

DIAPENTE, in Greek music; the interval of the fifth.

DIAPER, a kind of textile fabric, formed either of linen or cotton, or a mixture of the two, upon the face of which a figured pattern is produced by a peculiar mode of twilling, or tweeling. Diapers, which, excepting damasks, are the most ornamental kind of twilled cloths, are chiefly used for table-linen, fine towels, &c.

"The word diaper," observes Mr. Planché, in his 'History of British Costume,' "is derived by some writers from 'd'Ipres,' that is, 'of Ypres,' a town in Flanders, famous for its manufactory of rich stuffs and fine linen before the year 1200." "Ducange," he adds, "derives it from the Italian 'diaspro,' the jasper, which it resembles in its shifting lights; but the first is by far the most plausible conjecture; and though we read of diapers of Antioch, it is only because Ypres having given its name to its peculiar manufacture, any similar cloth received the same appellation."

In decorative painting, and in the ornamenting of glass, the term *diapering* is sometimes applied to a small delicate pattern introduced to diminish the appearance of baldness where a considerable space is covered with one colour, and thus to relieve the eye, without forming any part of the main design. In heraldic painting, especially, it is often resorted to, particularly where the juxtaposition of considerable masses of black and white might prove unsightly; but in all such cases it should be remembered that the diapering forms no part of the heraldic bearing.

DIAPHANOUS. [TRANSPARENCY].

DIAPHORETICS, or SUDORIFICS, are agents which increase the natural exhalation of the skin, or restore it when suppressed. Nothing better exemplifies the doctrine that remedies are only relative agents than this class of medicines, as their power to produce perspirations depends invariably upon the state of the patient and the circumstances in which he is placed, such as the temperature and humidity of the air by which he is surrounded. Many medicines which cause a flow of perspiration when the patient is kept warm, will produce, when he is in a cool temperature, an increased action of the kidneys and an augmented secretion of urine.

Their effects as diaphoretics are attempted to be accounted for by reference to two principles; 1, by increasing the action of the cutaneous vessels; 2, by increasing the vascular action of the whole system. Those diaphoretic remedies which seem to act according to the first principle produce their effects either by external application, such as the stimulus of heat, especially as proved by the hot-air bath, or as medicinal substances which enter the circulation and stimulate the cutaneous vessels by contact, such as mercurial preparations, some saline diaphoretics, and, most markedly, sulphur, which is evidently carried undecomposed to the cutaneous vessels and excreted by them; or, lastly, by acting on the surface sympathetically through the medium of the stomach, such as warm drinks, antimonial preparations, &c.

Those diaphoretic agents which seem to act according to the second principle are:—violent muscular exercise, carbonate of ammonia, guiacum, alcoholic stimulants, &c.

Diaphoretics are in general used to restore the cutaneous discharge when, from the action of cold or wet upon the system, it has been suppressed, and accordingly they are useful in common catarrh, rheumatism, or diarrhœa proceeding from cold. They are likewise of great service in fevers, the restoration of the secretion of the skin, if it be warm and gentle, not cold and clammy, often proving critical, and the precursor of recovery. In many cutaneous diseases diaphoretics are valuable agents, and for this purpose baths, either the natural warm baths or vapour baths, are used; but in such diseases the perspiration produced by exercise, or during a course of training, is decidedly the best diaphoretic. Some forms of indigestion are relieved or cured by causing an increased action of the skin, to effect which exercise is likewise the best agent.

It is worthy of remark, that the profuse and wasting perspirations which accompany the hectic of consumption are frequently more effectually checked by diaphoretics, especially the compound ipecacuan powder, than by any other means, except oxide of zinc.

(Young *on Consumption.*)

DIARRHŒA (διάῤῥοια), flux, looseness, purging, the frequent discharge from the bowels of more limpid stools than natural. The most obvious and common cause of this disease is the direct application of some stimulating substance to the inner or mucous surface of some portion of the alimentary canal, as articles of food and drink of too stimulating a quality, or, though wholesome in kind, taken in too large a quantity. Undressed or indigestible vegetables, whether acid or sweet, cucumbers, melons, mushrooms, different kinds of salads, fruits, especially plums, stale and decayed vegetables, animal food approaching to the putrescent state, as stale fish, high game, &c., contain matters either not easily digested, or when digested of so stimulating a quality as to irritate the mucous surface of the intestine, and to produce diarrhœa. Water tainted with putrid vegetable or animal matters, or loaded with certain kinds of living or dead animalcules, is no uncommon cause of diarrhœa. When a great mixture of different kinds of food and drink, in large quantities, though wholesome in kind, is taken into the stomach at one meal, it often produces a sudden attack of diarrhœa. Even a draught of cold water, beer, or milk, especially if the individual be overheated at the time, will often almost immediately occasion the same result. Soured or turned milk is a frequent source of diarrhœa amongst children. Many medicines and poisons are substances which prove directly and powerfully irritating to the stomach and intestines. The large class of purgative medicines and the poisons called irritants are of this kind. Purgative medicines, given in a certain quantity and at certain intervals ascertained by experience, produce a certain degree of diarrhœa, which the physician purposely excites for the accomplishment of various objects. Given in very large doses, or in ordinary doses when the system is in a state of peculiar irritability, they sometimes occasion an excessive diarrhœa, which continues longer than usual, and so produce that species of diarrhœa which is called hypercatharsis.

In the state of health various fluids are poured into the stomach and alimentary canal for the purpose of dissolving the aliment and assisting in its assimilation. To accomplish the purpose for which they are secreted from the common mass of blood, these fluids must be in certain quantity, and must possess a certain degree of stimulating power. But in various states of the system, from being bland in their sensible properties, and only moderately stimulating in physiological action, they become greatly increased in quantity, and highly irritating in quality. Of these fluids the principal are the gastric, the intestinal, the pancreatic, and the biliary. The secretion of the gastric juice may be altered in quantity and quality, in consequence of which it may be incapable of properly dissolving the aliment, which therefore may be sent from the stomach into the intestines in an acrid and irritating state, and so produce diarrhœa. The pancreatic juice may also be altered in quantity and quality, and become highly irritating; and the bile is sometimes poured out in greater quantity than usual, and of a more than ordinary acrid quality, and in both ways is a frequent cause of diarrhœa. Moreover, the entire surface of the stomach and intestines is crowded with secreting organs, mucous follicles, from which a quantity of fluid is constantly poured out, constituting the chief portion of the evacuations passed when little or no food has been taken, and which probably also affords the principal part of the matter of the liquid stools that occur in diarrhœa. In many states of the system, and from numerous irritating substances applied to their surfaces, the secretion of these bodies becomes excessive in degree, and highly acrid and irritating in its nature.

The quantity of matter from this source may be indefinitely increased by whatever is capable of occasioning a greater efflux of blood than natural to the mucous surface of the alimentary canal. Hence it may be superinduced by all the other causes of diarrhœa—indigestible food, wholesome food in too large a quantity, disordered states of the digestive fluids, &c., and from increased afflux of fluids from other parts of the system, as from cold applied to the surface of the body and suppressing perspiration, which may determine a greater quantity of fluids to the intestines. Great alternations of temperature will, in many constitutions, produce the same result. Suppressed evacuations, checked menstruation, the retrocession of eruptive diseases, as measles, scarlatina, &c., are often immediately followed by diarrhœa. Even mental emotion is capable of producing it in some irritable and nervous constitutions to a great degree; and when under the influence of such emotions, the slightest excess in food or drink, or the slightest quantity of irritating aliment, will be succeeded by numerous and liquid stools. Irritation in a distant part of the body often induces increased action of the intestines, and occasionally diarrhœa, as the irritation of the gum in dentition. The mucous surface of the whole alimentary canal is highly sensitive and irritable in infants and children, and food improper in quantity or quality is exceedingly apt to induce diarrhœa in them, and if the irritation in the stomach and intestines from this cause be kept up long, irreparable and fatal disease is sure to be induced. Slight errors in diet on the part of the mother, and even an irritable state of mind, will disorder her milk to such a degree as to produce distressing diarrhœa in her infant. The excitability of the capillary arteries, the mobility of the muscular fibres, and the sensibility of the whole nervous system during the early periods of life, render the young much more susceptible to all the causes of diarrhœa than the adolescent and the adult; and the more tender the age the greater this susceptibility.

By whatever cause diarrhœa may be excited, it is seldom that the increased discharge of liquid stools from the intestines is the only symptom present. It is commonly preceded by nausea, and in general more or less uneasiness is felt in the stomach and intestines, which sometimes amounts to severe griping pain, often accompanied with flatulence. In severe cases the abdomen is distended, and even tender to the touch; the nausea passes into vomiting; and the pain, especially around the navel or in the course of the colon, becomes intense, somewhat relieved, perhaps, after each evacuation, but soon returning with undiminished severity. The number of evacuations may vary from three or four to twenty or thirty in the twenty-four hours. Of course the sudden loss of so large a portion of the more fluid part of the blood as is contained in these watery evacuations deprives the system of a proportionate quantity of stimulating and nutritive matter, and accordingly there is often great prostration of strength, and a striking expression in the countenance and attitude of languor and debility. In slight cases the pulse is little if at all affected; but when the pain is severe and the discharge copious, the pulse is quickened, and at an advanced stage of the attack is generally small, weak, and much increased in frequency. The tongue is loaded, and in certain forms of the disease is intensely red at the edges and tip, and the papillæ are large, prominent, and of a bright red colour, shining through a thick coat of fur. The urine is generally diminished in quantity. The skin, at first hot, towards the termination of the attack is unusually cold and chilly, and is peculiarly incapable of resisting the influence of a cold and damp atmosphere.

The nature of the matters contained in the evacuations varies remarkably, and affords important indications of the seat and state of the disease. Several varieties of the disease have indeed been founded on those appearances, and diarrhœa has accordingly been divided into fæculent, bilious, mucous, serous, chylous, lienteric, &c., but the causes of the disease afford more fixed and determinate characters for its distribution into species. Of these there are commonly enumerated the following: diarrhœa *crapulosa*, from food improper in quality or quantity; diarrhœa *biliosa*, from bile more abundant or more acrid than natural, as from the heat of summer and autumn, co-operating with errors in diet; diarrhœa *serosa*, from increased vascular action of the mucous surface of the alimentary canal, induced by whatever occasions a preternatural afflux of blood to the mucous surface; diarrhœa *mucosa*, from increased secretion of the mucous follicles, which may be induced by almost any of the ordinary exciting causes of diarrhœa; diarrhœa *lienterica*, the aliment passing in the evacuations almost unaltered, occurring principally in children about the first and between the first and second dentition, and occasioned by the ordinary exciting causes of diarrhœa.

The duration of this disease must of course be materially influenced by the persistence of the cause that excites it. Its ordinary varieties being generally dependent on temporary causes, are of short duration; but the increased secretion of bile by the liver, and of mucus by the mucous follicles, and the irritation of the intestinal canal from dentition, may be protracted to an indefinite period; and the disease dependent on the excited state of these organs may consequently become chronic, continuing for months together to harass the patient and enfeeble the constitution. In these cases, when a cure is apparently effected, very slight causes are capable of bringing back the disease; and during the period of convalescence the utmost caution is always necessary to avoid errors in diet and any exposure to cold or wet.

The immediate danger from a very severe attack of diarrhœa, or from its passing from the acute into the chronic state, is, that it should terminate in acute inflammation of the bowels (enteritis); or chronic inflammation and ulceration of the bowels (dysentery); or intus-susception (the passing of one convolution of the intestines into another), induced by the increased peristaltic action of the bowels; or enlargement, hardening, and obstruction of the mesenteric glands, and the consequent wasting of the body (marasmus), one of the most common forms of disease by which the existence of infants and children is cut short.

There are several diseases with which diarrhœa may be confounded, from which it is important that it should be distinguished. From the far more serious malady termed dysentery it is distinguished by the absence of fever, by the absence of blood in the evacuations, and by the absence of the painful, distressing, and ineffectual desire to evacuate the contents of the bowels which is called tenesmus. It is distinguished from cholera by the absence of spasms of the muscles, so constant and distressing in the latter disease, by the slighter degree or the total absence of vomiting, and by the milder character and the much less rapid progress of the entire disease. But the bilious and even the pestilential cholera frequently commence with one or other of the preceding forms of diarrhœa. Life often depends on the clearness and promptitude with which the diagnosis is made between diarrhœa from irritation, constituting the crapulous and bilious forms of the disease, and the diarrhœa from inflammation, which often appears under the serous and mucous forms. The diagnosis is chiefly to be drawn from the marked difference in the constitutional symptoms when the diarrhœa is the consequence of an inflammatory state of the internal surface of the intestines. In this case there is always present a greater or less degree of fever; the skin is hot, or alternately hot and chilly; the pulse is more or less excited, and the strength prostrate. The pain in the bowels is obscure and dull rather than griping, the abdomen is tender on pressure, and it is in this case more especially that the tongue is preternaturally red at the edges and the tip, and that its papillæ are enlarged and red.

Though diarrhœa is often a trifling disease, and even a remedial means adopted by nature to prevent the occurrence of more serious evils, yet the serous and mucous forms of it, more especially when they pass into a chronic state, are apt to terminate in dangerous and fatal maladies, and their management requires great and persevering care. Instances are by no means unfrequent in which the ultimate event proves fatal, in consequence of their neglect, or of the medical treatment and the remedies being injudicious. Indeed the treatment of diarrhœa in general requires much discrimination, for a very trifling form of it is easily converted by mismanagement into a highly dangerous disease. The chief difficulty is to detect the exact nature of the exciting cause, and the exact condition of the excited organ, which alone can guide to the selection of one of two opposite plans of treatment, the administration of purgative or of opiate medicines. If the irritation arise from too large a quantity of stimulating food and drink, abstinence alone is sufficient to effect a cure; but if, notwithstanding the abstinence from food, the disease continue, it is necessary to ascertain whether the irritation be kept up by the retention of irritating matters, or whether the alimentary canal itself be in a preternaturally irritable and excited state. If the former, purgative medicine of some kind or other is indispensable, but the choice of the purgative is by no means a matter of indifference. It should have the power of evacuating the contents of the bowels without irritating the mucous surface. For this purpose castor oil is one of the best medicines; or, if a somewhat stronger purgative be required, infusion of senna with manna. It is often attended with the best effects to combine a few drops of laudanum with the aperient. When the irritating contents of the stomach and intestines are removed, a mild and frequently repeated sedative should be prescribed, one of the best of which consists of two drachms of almond oil with two drachms of mucilage of gum arabic in an ounce of rose or peppermint water, with from five to ten drops (according to the severity of the case) of laudanum, or half a drachm or more of the tincture of hyoscyamus. If the secretions are disordered, five grains of blue pill or of hydrargyrum cum creta, with the same quantity of the compound powder of ipecacuanha, taken every night, or every other night, at bed time, with a tea spoonful of castor-oil, containing a few drops of laudanum, the morning following, will soon restore them to a healthy state. Of course the diet should consist only of the mildest alimentary substances; for as long as the alimentary canal continues irritable, food and drink, even of the ordinary stimulating properties, will keep up or re-excite the diarrhœa.

The exciting cause of the biliary variety of diarrhœa is often inflammation of the liver (hepatitis). When there are present any indications of this, blood-letting, or local bleeding by cupping or leeches, must precede all other remedies; and the abstraction of blood must be repeated at short intervals until the inflammatory state of the liver is removed; then mild mercurials, with mild purgatives, are necessary. This is by no means a variety of diarrhœa which can be cured by opiates. The exhibition of any remedies of this class, which, when judiciously managed, are sometimes highly advantageous, requires peculiar discrimination and skill. In the serous and mucous diarrhœa, when there is present no proper fæculent matter, all this having been previously discharged, it is absurd to give purgatives; such medicines can only still further irritate the over-excited organs. Leeches to the abdomen, the warm bath, demulcents with opiates, the chalk mixture, and the strictest regulation of the diet, are necessary.

The diarrhœa, so easily excited, so constantly present, in infants and young children, requires a peculiarly cautious management. When it is connected with dentition it is pregnant with danger to stop the discharge, or even to restrain it, unless it becomes excessive, and then it should be moderated, not stopped; and the mildest means should be employed to accomplish this object, which should never be attempted without at the same time paying the strictest attention to the diet, air, and exercise of the child. Death is often produced in infants at this critical period of the infant's life by the exhibition of opiates to stop this discharge. The proper remedies are the choice of the blandest articles of food, the avoidance of over-feeding, two or three grains of hydrargyrum cum creta at night, and the tepid bath.

DIARY, from the Latin *Diarium*, which again is from *Dies*, a day. The original and proper meaning of the word *Diarium* among the Romans was the daily allowance made to slaves for their sustenance, as *Menstruum* was their monthly allowance. *Diurnum* was another word for the same thing. [Acta Diurna.] In later times however either word came to be used for a note-book, or other register of daily occurrences, which had formerly been called (after the Greek) an ephemeris. It is only in the sense of a daily register that the word diary is used in English; and, naturally enough, it is commonly understood to imply specifically a register of occurrences in which the writer has had a personal share, or which have at least in some sort come under his own observation by having happened in his own time. For instance, although a history of the transactions of a former age, composed in a particular form, might be entitled annals, such a history, however minute, would scarcely in any case receive the name of a diary. A diary is etymologically the same thing with a day-book or journal; the latter word being a modernised form of diurnum, as diary is of the synonymous diarium of the same parentage. The French language has only the form *journal;* the Italian, like the English, has both forms, *diario* from *diarium*, *giornale* from *diurnum*, both ultimately from *dies*.

DIASCHI'SMA, a term employed in ancient and in speculative Music, but not in practical use among modern musicians. It is the half of a minor semitone or diesis. [Diesis.]

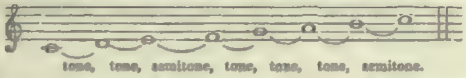
DIASTASE, a peculiar ferment formed during germination. It is prepared by reducing freshly germinated barley into a pulp, with half its weight of water, and then pressing out the liquor strongly. To the clear liquid just sufficient alcohol is to be added to destroy its viscidity, and allow of its being filtered; by this an azotised substance is precipitated, which must be considered as vegetable albumen, since it coagulates at 167° Fahr. Having separated this, alcohol is to be again added as long at the liquid becomes turbid; the precipitate is to be purified by solution in water and precipitation by alcohol repeatedly; the precipitate is at last to be dried in thin layers upon glass at a temperature between 104° and 122° Fahr.

The properties of diastase are the following: It is solid, white, not crystalline, soluble in water, but insoluble in moderately strong alcohol; the aqueous solution is nearly tasteless, and without any chemical action, not precipitating subacetate of lead. The aqueous solution quickly changes, becoming acid; dry diastase undergoes the same change in a longer time, but when boiled in water the alteration is immediate. Common malt is stated in general not to contain more than 1-500th of its weight of diastase; one part of it is sufficient to convert 2000 parts of starch, thickened with water, into a mixture consisting of much dextrine and a little sugar. It has not yet been obtained absolutely pure. [FERMENT.]

DIATESSARON, in Greek music, the interval of the fourth.

DIATHERMANISM. A body which is transparent to light is said to be *diaphanous:* one which is transparent to heat is said to be *diathermanous*, and the branch of science which treats of such bodies is called *diathermanism.* Bodies which do not transmit heat, are said to be *athermanous.* [HEAT.]

DIATON'IC, in Music (*διὰ, through*, and *τόνος, a tone*), a term applied to the first of the three ancient genera, and of the three modern scales, but in both cases rather improperly, because the intervals of the Greek genus and of the scale now in use consist not only of tones, but also of semitones. The *Major Diatonic Scale* of the moderns proceeds thus:—



The Diatonic genus of the Greeks, as exhibited in their several *modes*, comprised five tones and two semitones, differently disposed: that of the Lydian mode, according to Sir Francis Styles ('Transactions of the Royal Society,' 1760), corresponded, as regards the position of the intervals, to our major diatonic scale. [SCALE.]

DIBENZANILIDE. Synonymous with *phenylbibenzamine, dibenzöyl-phenylamide*, and *phenyl-dibenzamide.* [BENZOIC GROUP; *Phenylbibenzamine.*]

DIBENZÖYLIMIDE. ($C_{28}H_{13}NO_2$). A yellow crystalline body, obtained by the action of ammonia upon oil of bitter almonds.

DIBENZÖYLPHENYLAMIDE. [DIBENZANILIDE.]

DIBROMANILINE. [ANILINE.]

DICETYLANILINE. [CETYL, *Compounds of.*]

DICHLORANILINE. [ANILINE.]

DICHLORISATIN. [INDIGO.]

DICHROISM. When light is transmitted through a crystallised body, and its colour is found to vary according to the position of its axis with respect to the incident pencil of light, the crystal is said to possess *dichroism*, or double colour, from *δὶς* and *χρόα.* [LIGHT; POLARISATION.]

DICTA'TOR was the highest extraordinary magistrate in the Roman republic. Though the name obviously contains the element *dic* (from *dico*), it was doubted by the Roman writers whether the title had reference to the mode of his nomination or to his power. He was also called by the old name of Magister Populi, and in Greek *δισύπατος*, or "double consul." After the expulsion of the kings the consulship was established. The two consuls possessed the same power as the kings in the administration of the state and the command of the army, yet their authority was subject to some restrictions, and principally by the appeal that could be made from their decisions. [CONSUL.] The two consuls, possessing equal authority, often differed in their views and opinions; a circumstance which necessarily caused jealousy and disunion, particularly in the command of the army when on active service. In extraordinary emergencies, the republic therefore required a single magistrate, invested with ample authority. Such circumstances led to the establishment of the dictatorship. The first dictator was created about the year 253 A.U.C., or 501 B.C. (Liv. ii. 18.)

The dictator united in himself the power of the two consuls; and the authority of all other magistrates, except that of the tribunes, ceased as soon as he was appointed. He possessed the whole administrative power of the state, and the command of the army without any restrictions. (Dion Cassius, according to Zonares, vii. 13, where a reference to a lost book of Dion is given. Dion Halic., v. 70, 73.) He had the power of life and death, and there was no appeal from his decision. Both within and without the city he was attended by twenty-four lictors, with their fasces and axes. The dictators were not chosen, like the other magistrates, in the comitia, but they were appointed by one of the consuls, in conformity with a vote of the senate. Sometimes the senate itself appointed the dictator, and in some instances he was elected by the comitia. At first he was taken only from the patrician order, but afterwards (B.C. 356) also from the plebeians. After his election, the dictator nominated the master of horse (magister equitum), who commanded under him. It was only when the state was menaced by sudden danger from within or without that a dictator was nominated; but in the course of time a dictator was elected to preside at the elections in the comitia, when the consuls were abroad, and therefore could not preside; and also on some other public solemnities. (Liv. vii. 3; viii. 18 and 23.) The dictator continued in office for six months, but he commonly resigned as soon as the danger was over which had led to the nomination. The dictator was not allowed to leave Italy, or to enter the city on horseback. Yet there are instances in which the dictator left Italy, as for example in the first Punic War, when a dictator commanded in Sicily. The rule that he should continue in office only six months was also neglected; Sylla and Julius Cæsar were nominated perpetual dictators, the former in the year 81 B.C., and the other after his victory at Pharsalus. The office seems never to have been filled from B.C. 202, to the time when Sylla, the head of the oligarchical party, was made perpetual dictator. J. Cæsar, who was the head of the democratic party, or perhaps rather chose that party merely that he might, by being at the head of one of the great divisions which distracted the state, prepare the way for his own unlimited power, after being dictator five times, became dictator for life. Augustus declined the office, though offered to him by the people (Suetonius, 'Aug.' 52), and the title of dictator was never assumed by the emperors of Rome.

These are the received opinions as to the Roman dictators; but in Niebuhr's Roman history we find other views of the subject, to which we shall briefly advert. According to him, the dictatorship was of Latin origin and was introduced from the Latins among the Romans. The object of the Roman dictatorship was to evade the Valerian laws, and to establish the power of the patricians over the plebeians; for the appeal granted by those laws was from the sentence of the consuls, and not from that of the dictator. The later Romans had but an indistinct knowledge of the dictatorship of the ancient constitution. Dion Cassius is in error, when (without excepting the patricians) he asserts that in no instance was there a right of appeal from the dictator, and that he could condemn knights and senators to death without a trial. Dionysius is also in error, when he says, that the dictator decided on every measure according to his own pleasure. It is incorrect to suppose that the appointment of the dictator in all cases rested with one of the consuls; for the conferring of kingly power (such as that of the dictator was) could never have been intrusted to a single person. The pontifical books have preserved so much as this, that the dictator was nominated by the senate, and that the nomination was approved by the people. As the plebeians increased in power, the dictatorship was seldom required, and then only for matters of less importance; and in such cases the nomination was left to the consuls.

(For a general sketch of the dictatorial power, the reader may consult Creuzer, *Abriss der Römischen Antiquitäten*, &c., Leipzig, 1824; Niebuhr's chapter *on the Dictator*, and his *Remarks on the Relationship of the Dictator and the Master of the Horse*, vol. i., Engl. Trans.)

DICTIONARY, the English form of *Dictionarium*, a word of low or modern Latinity, which from its etymology should signify properly a book of phrases or modes of expression. The term however has been generally applied to any work which professes to communicate information on an entire subject, or entire branch of a subject, under words or heads digested in the order of the alphabet. This alphabetical arrangement appears to be the distinctive peculiarity of what is called a dictionary; but to constitute the work a dictionary, it should seem that there must also be attached to each of the terms, so arranged, some explanation or interpretation. Thus, an index, in which words or titles are merely put down in alphabetical order, with nothing more than a reference to some page or passage appended to each, is not a dictionary. The alphabet itself is not a dictionary. Again, a dictionary, however arbitrary or artificial may be the order in which its parts are distributed, must profess some unity and completeness of design. It must profess, as has been said, to go over a whole subject, or field of knowledge, of greater or less extent. Thus a mere list of miscellaneous particulars, even with explanatory remarks or comments annexed, is not a dictionary, but a catalogue. A collection of plays or of pamphlets might be arranged in the order of the alphabet, but would not on that account make a dictionary. That name is not applicable, and is never given, even to the most extensive enumeration and account of things which are merely brought together, without constituting when collected a natural system or complete body of knowledge.

Within the limitations noted, the term dictionary is applied to works on all kinds of subjects, and with every diversity of object. Dictionaries have sometimes been divided into three classes or descriptions: 1. Dictionaries of words. 2. Dictionaries of facts. 3. Dictionaries of things. And although objections may be made to the principle of this distribution (as has been done by D'Alembert in the 'Encyclopédie,' article *Dictionnaire*), it is sufficiently convenient for practical purposes, and we shall therefore adhere to it in what we have now to say.

I. *Dictionaries of Words.*—This is the original application of the word dictionary, and the sense in which it is commonly understood when it stands alone. It answers in this sense to the Greek lexicon, and although etymologically that term, like the term dictionary, ought perhaps to signify a book of phrases or modes of expression, yet among the Greeks it seems rather to have denoted a book that explains words. A dictionary or lexicon, indeed, usually combines an explanation of phrases with an explanation of single words. When it contains nothing beyond an explanation or translation of single words, it is more distinctively called a vocabulary or word-book. The word vocabularium, we believe, is not found in the Latin of antiquity, any more than dictionarium. A glossary, in Latin *glossarium*, which is used by the later classics, from the Greek *glossa* (*γλῶσσα*), "a tongue" or "language," is generally understood to mean an explanation, more or less diffuse, of terms of unusual occurrence. Among the Greeks themselves, indeed, *glossa* was used for a foreign or otherwise peculiar word or form of expression. (Aristot., 'Poet.,' c. 38.) As there is nothing in the etymology of the term glossary, however, to confine it to this explanation, many examples may be found of its employment in a more extended sense. Some dictionaries profess to have more peculiarly for their object the explanation or interpretation of phrases; such, for example, as the well known volume on the Latin language entitled 'Phraseologia Generalis,' by William Robertson, 8vo, Camb. 1681; and Tarver's 'Phraseological Dictionary,' in French and English, 1850. Some dictionaries and vocabularies apply only to some particular author or work; such as Damm's Lexicons or Concordances, as they are called, of Homer and Pindar, since combined into the 'Lexicon Homerico-Pindaricum,' the 'Lexicon Ciceronianum' of Marius Nizolius, &c. Such dictionaries, when well compiled, are among the most valuable aids the student can avail himself of. Nor are they of use only in studying the authors of antiquity; the works of some modern writers have been very ably illustrated in this way, as, for instance, by Archdeacon Nares in his glossary to Shakspere and his Contemporaries, 4to, London, 1822. Even a mere verbal index, with little or no explanation of the meanings of the words, is often much more useful than a professedly interpreting dictionary, by merely bringing together or pointing out by reference the different passages in which each word is used, so that they may be compared with one another. Such mere indexes as those attached to the 'Delphin Classics' are of great value in this way, in addition to their proper use of enabling any passage to be found of which even a single word is recollected. Few of our English classics have been illustrated by such complete verbal indexes; there is one to 'Milton's Paradise Lost,' 12mo, London, 1741. Ayscough's 'Index to Shakspere' is only an index to the "remarkable" passages and words; and although its professed design is "to point out the different meanings to which the words are applied," it is not very successfully compiled for that purpose. Mrs. Cowden Clarke's Concordance is far more complete. Indexes of this description serve in fact the same purpose with Concordances, although that term has been for the most part confined to works relating to the Scriptures. [CONCORDANCE.] Some works entitled dictionaries, indeed, comprehend concordances more or less complete; as, for instance, Schleusner's 'Novum Lexicon Græco-Latinum in Novum Testamentum,' and the Ionic lexicon of Schweighäuser, which is a sort of concordance to Herodotus, and that to Polybius by the same scholar.

Some of these dictionaries to particular authors, or works, have exclusively or principally in view the illustration of the style of the author, or his use of particular words. One of the best of these is Ernesti's 'Index Latinitatis Philologico-Criticus' to Cicero. This work in fact, although styled merely an index, is much more a dictionary of interpretation and commentary than the lexicon just mentioned of Nizolius, which, however, is much the more minute and extensive index of the two. The instance may serve to show with what latitude the two titles are applied. And the title of index, it may be added, has been sometimes given to works which are not really indexes in any respect, but simply dictionaries or vocabularies. We may mention as an example, 'Olai Vereli Index Linguæ Veteris Scytho-Scandicæ, sive Gothicæ, opera Olai Rudbeckii editus,' fol. Upsalæ, 1691, which is merely a vocabulary of the Gothic. Dictionaries of languages have also been published under many other titles. A thesaurus, or treasury, is a very common title of such a book. Thus Faber's Latin dictionary is styled 'Thesaurus Eruditionis Scholasticæ,' and H. Stephens' Greek lexicon is entitled 'Thesaurus Græcæ Linguæ.' Edward Philips entitles his English dictionary a 'World of Words.' In some cases an attempt has been made by means of a dictionary or index, not only to point out the writer's use of particular words, or their meaning in particular passages of his works, but also to give an abstract of his text. This has been done in the index to Hippocrates, by Fœsius, entitled 'Œconomia Hippocratis Alphabeti serie distincta, in qua Dictionum apud Hippocratem omnium, præsertim obscuriorum, usus explicatur, et velut ex amplissimo Penu depromitur, ita ut Lexicon Hippocrateum merito dici possit,' fol. Francf. 1688. In 1677, Elisha Cole published in London, in 8vo, 'An English Dictionary; explaining the difficult terms that are used in Divinity, Husbandry, Physick, Philosophy, Law, Navigation, Mathematics, and other Arts and Sciences.' Of dictionaries of words also, some are dictionaries of etymologies, some of the quantities of syllables (as the common Latin 'Gradus ad Parnassum,' and Morell's 'Thesaurus Græcæ Poeseos, sive Lexicon Græco-Prosodiacum,' improved and enlarged by Maltby); some of terminations (as in English, Walker's 'Rhyming Dictionary'), and Hoogeveen's 'Dictionarium Analogicum Linguæ Græcæ.' Some dictionaries of the oriental tongues and of the Greek tongue exhibit the words arranged according to their supposed roots; and some Latin dictionaries have also been constructed upon this plan. Of professed dictionaries of derivations one of the most elaborate, though it is far from being a correct or philosophical work, is the 'Entymologicon Linguæ Latinæ' of G. J. Vossius. Others are the 'Dictionnaire Etymologique de la Langue Française,' of Menage; the 'Origines de la Langue Italienne,' of the same author; the 'Etymologicon Linguæ Anglicanæ,' of Stephen Skinner, fol. 1671: and the 'Etymologicon Anglicanum' of Francis Junius, fol., Oxon, 1743. A very ambitious attempt has been made by Mr. Whiter in his 'Etymologicon Magnum, or Universal Etymological Dictionary on a new plan,' 3 vols. 4to., Camb. 1800—1822, to construct a dictionary of the elements of all human language. Mr. Booth, in his 'Analytical Dictionary of the English Language,' has set an example of perhaps the happiest mode in which an account of words can be given according to their etymologies or affinities. By making each radical term the text of a short essay, in the course of which the history of all its derived and connected terms is traced and illustrated by quotations, references to manners and customs, and anecdotes of various kinds, the writer has rendered his dictionary as entertaining as it is instructive, and adapted it not only for occasional consultation but for continuous reading. Dr. Chevenix Trench has likewise made valuable additions in this direction.

Any account of the dictionaries of particular tongues would be out of place here. There is a 'Table Alphabétique des Dictionnaires,' by Durey de Noinville, published in 1758, which however is asserted to be very incomplete, even for that time. A very elaborate dissertation on lexicons and glossaries in general, and on those of the Greek language in particular, by P. J. Maussacus, is inserted in most of the editions of the Greek lexicon of Harpocration, entitled 'Lexicon Decem Oratorum;' and the same subject has also been treated by several other writers who are enumerated in Morhoff's 'Polyhistor,' lib. iv. cap. 7. In the portion of Morhoff's third book, from chapter 4th to chapter 9th inclusive (vol. i. pp. 743–830, edit. 1747), is given an account of the principal dictionaries of the modern European tongues, of the oriental tongues, of the Greek, and of the Latin tongues. See also De Bure's 'Bibliographie Instructive,' vol. iii., p. 1–86.

In some dictionaries the words are explained in the same language to which they belong; in many others the words of one language are interpreted by corresponding words in another language. In some the interpretation or translation is into several languages; as, for instance, in Minsheu's 'Dictionary of Eleven Languages, namely, English, Welsh, German, Dutch, French, Italian, Spanish, Portuguese, Latin, Greek, and Hebrew,' fol. London, 1617: and in a dictionary printed at St. Petersburg in 3 vols. 4to., in 1785, in which the words and phrases are given in French, German, Russian, and Latin.

Although, as Maussacus in his Critical Dissertation just noticed has taken great pains to prove, books both of γλῶσσαι, or unusual words, and of λέξεις, or idioms, are frequently referred to or mentioned by the Greek and Latin grammarians and other writers, it does not clearly appear that all of these were what we should now call dictionaries, that is to say, were collections of vocables and phrases alphabetically arranged. The oldest extant Greek lexicographer is Appollonius the Sophist, a contemporary of Augustus; his work entitled Λέξεις Ὁμηρικαί, or 'Homeric Words,' though much interpolated, is very useful. All the other original Greek lexicons and glossaries we have, such as the 'Onomasticon' (or collection of Synonyms) of Julius Pollux, the lexicons of Suidas, Harpocration, and Hesychius, and the 'Etymologicon Magnum,' sometimes attributed to Marcus Musurus, although of the authors of some of them the exact age is disputed, were undoubtedly compiled subsequent, and most of them probably long subsequent to the commencement of the Christian era. It is supposed, indeed, that they were founded upon older compilations of the same kind; but of the form of those lost works we know nothing. It may be reasonably doubted if either the Greeks or Romans were in the habit of making use of dictionaries in studying a foreign language or dialect, as has been the general practice in modern times. They would seem rather to have uniformly followed what may be called the natural method of learning the language from conversation with those who spoke it, being the method by which we all learn the language we acquire both most easily and most perfectly, our mother tongue, and that by which alone a real knowledge and command of any language can be acquired. Although, however, the utility of a general dictionary of a language as an instrument either for teaching the language to youth in schools, or for enabling a student to master it in any circumstances, may well be questioned, there are obvious considerations which make it desirable that we should possess such dictionaries of all languages. When a dictionary of a language professes to be more than a mere vocabulary, it is usual for it to contain along with the interpretation or explanation of the meaning of each word, some account of its etymology or derivation, and also of its grammatical usage. Except when the dictionary is exclusively etymological, perhaps all that ought to be attempted in regard to the foreign extraction of words is to note the language from which each may be supposed to have been immediately borrowed. But merely to append the supposed original word of the foreign language, as is generally done, conveys little valuable information in any case, and is very apt to lead to misconception. If it is desired to exhibit the nature of the change which the forms of the words have undergone in passing from the one tongue to the other, this will be better done by a short statement on the subject once for all, in which the several modes and incidents of the transference should be systematically arranged and illustrated by examples, and the principle of each explained. It would be fully of as much importance however that in every dictionary of a language the connection of each word with other words in the same language, or the native root from which each has sprung, should be distinctly marked whenever it is not obvious. This reference of each word to the proper family to which it belongs contributes more to make its meaning clear and to point out its correct use than any definition can do. And such a notice of the root of the word would naturally lead to, and should be followed by, as precise a statement as possible of its primitive and most simple meaning; after which should come a chronological deduction of the changes it has undergone, as far as they can be traced, both in signification and in form, the whole definition being concluded by an explanation of its metaphorical and other secondary or transferred meanings. If its use in each sense can be illustrated by an example, such quotations are, for various reasons, in the highest degree satisfactory and valuable. Any remarkable uses of the word in particular passages of standard authors ought at least to be adverted to and explained; and a notice of its peculiarities of construction, or the manner in which it is connected with other words in a sentence, should never be omitted. There are some dictionaries in which all this has been attempted, but perhaps scarcely one in which it has been quite satisfactorily executed. Among the most carefully compiled dictionaries of modern languages are that of the Italian, entitled 'Vocabolario degli Academici della Crusca,' extended in the latest editions to 6 vols. fol.; and that of the French, entitled 'Dictionnaire de l'Académie Française.' But in both these works, especially in the latter, the design principally kept in view has been to guard the purity of the language. There is also a Spanish dictionary of great reputation, entitled 'Diccionario de la Lengua Castellana, compuesto por la Real Academia Española,' 6 vols. fol., Madrid, 1726, &c. In English, Johnson's Dictionary has been accounted the standard work of its class ever since its appearance, in 2 vols. fol., 1755; but although it was a great achievement for an individual, and its definitions in particular afford remarkable evidence of its author's ingenuity and command of expression, it is in many respects far from being what a dictionary should be. Its etymological part is very poor; and it is characterised throughout by want of method and of philosophical views. Some useful matter has been added to the edition of the English Dictionary (augmented to 6 vols. 4to.) edited by the Reverend Mr. Todd; but the philosophical character of the work has received no improvement in his hands. Dr. Richardson's Dictionary is formed on the principle of giving all the words consecutively that are derived from the same root. It appeared first in the 'Encyclopædia Britannica,' but was published, enlarged and improved, in 1826. Other dictionaries have been compiled containing collections of obsolete or provincial words. Among them may be mentioned, as belonging to Great Britain, that of Dr. Jamieson, 'An Etymological Dictionary of the Scottish Language,' in 2 vols. 4to, Edinb., 1808; Boucher's 'Glossary of Archaic and Provincial Words; a Supplement to the Dictionaries of the English Language, particularly those of Dr. Johnson and Webster,' which was carried no further than the word Blade, and only one part was published as a specimen, with a well-written introduction, in 4to, in 1832 [Boucher, in Biog. Div.]; Halliwell's 'Dictionary of Archaic and Provincial Words,' 2 vols. 8vo, 1850; and Thos. Wright's 'Dictionary of Obsolete and Provincial English,' in 2 vols. 8vo, 1857; Crabb's 'Technological Dictionary,' published in 2 vols. 4to, in 1823; and of which a new edition has been published in 1859; a work of a useful character, which might be extended and improved to advantage.

II. *Dictionaries of Facts.* This class comprehends dictionaries of history, biography, mythology, geography, archæology, and all others that deal chiefly or exclusively with events that have happened, or are supposed to have happened, or with facts that exist or have existed. Many of the principal works of this description are enumerated in the article Biography: and under Bibliography will be found an account of another large division of them. We may here observe that some of the old Greek lexicons already noticed were dictionaries of facts as well as of words; the lexicon of Suidas, for instance, is, in the greater part, made up of fragments of biography, history, and geography, and often contains large extracts from various writers both extant and lost. The work of Stephanus Byzantinus, sometimes entitled Ἐθνικὰ (the Ethnology), more commonly Περὶ Πόλεων (the Book of Cities, or rather of States), is chiefly a geographical and archæological dictionary, and is the oldest compilation of that description that exists. Its meagre details under each head assimilate it in some respects to an imperfect gazetteer. In modern times the number of dictionaries that have appeared, professing to present a view of a more or less extensive field of facts, has been very great. Besides the various historical, biographical, and geographical dictionaries, general and particular, and the bibliographical dictionaries, there are dictionaries of antiquities, of architecture, of heraldry, of painting, of music, of botany, of law, of legal decisions, of commerce, of medicine, of surgery, and of almost every other department of human knowledge. Opinions, indeed, considered historically, are themselves facts, and as such ought to be recorded and arranged in dictionaries as well as other facts. Discussion also often places doubtful facts in a clearer light, and a dictionary may be as convenient a vehicle for such discussion as any other book. But a most useful class of books, of which we have yet scarcely a specimen, would be a set of dictionaries or tabular expositions of facts, and nothing else. They would serve, among other purposes, as maps of the extent and boundaries of the different departments of human knowledge, and most useful directories in the prosecution of all inquiries having in view the enlargement of those boundaries. As of facts some are completely ascertained, others only probable, and others doubtful, three divisions answering to these descriptions might be given under each head, and a fourth might perhaps be advantageously added for improbable or confuted statements, although these last might be more scientifically exhibited in the table or dictionary of the facts forming the history of opinions.

This class of Dictionary, indeed, is becoming much in vogue for special subjects or branches of study; and the following titles of a few of the more characteristic will illustrate their nature:—'Dictionnaire des Sciences Médicales, par une Société de Médecins et Chirurgiens,' edited by F. P. Chauneton and F. V. Mérat, 60 vols, 8vo, Par. 1812-22; 'Universal-Lexikon der Praktischen Medecin und Chirurgie, von Andral Bégin, &c.,' 14 vols. 8vo, Leipz. 1844–48; 'Dictionary of Practical Medicine,' by J. Copland, 3 vols. 8vo, Lond. 1844–58; 'Cyclopædia of Anatomy and Physiology, with Supplementary Volume,' by R. B. Todd, 5 vols. 8vo, Lond. 1835-59; 'Dictionnaire généalogique, héraldique, chronologique et historique,' by M. D. L. C. D[es] B[ois], 7 vols. 12mo, Par., 1757-65; 'Dictionnaire géographique universel. Par une Société de Géographes,' 13 vols. 8vo, Bruxelles, 1839; 'Nouveau Dictionnaire d'histoire naturelle, appliquée aux Arts,' nouvelle ed., 36 vols. 8vo, Par. 1816-19; 'Dictionnaire Classique d'histoire naturelle,' par Audouin, Bourdon, and others, edited by Bory de St. Vincent, 17 vols. 8vo, Paris, 1822-31, of which a 2nd ed. published under the title of 'Nouveau Dictionnaire Classique d'histoire naturelle; ou repertoire des sciences naturelles et physiques. Rédigé par une Société de Naturalistes,' 2e édition, revue par M. B. S., 47 vols. 12mo, with an Atlas in 8vo, Paris, 1844-46; 'Dictionnaire des Sciences Naturelles,' edited by F. Cuvier, 61 vols. of text and 10 of plates, 8vo, Strasb. and Paris, 1816-45—with a 'Supplément et Atlas de Zoologie,' 2 vols. 8vo, Par. 1840-44; 'Dizionario delle Scienze Naturali: tradizione dal Francese, con aggiunte e correzioni,' (with plates) 26 vols. 8vo, Firenze, 1830–51; 'Dictionnaire de l'Industrie manufacturière, commerciale, et agricole,' par Baudrimont, Blanqui, &c., 10 vols. 8vo, Paris, 1831-41; 'Dictionnaire Raisonné de l'Architecture Française du XI au XVI siècle, par Viollet-le-Duc,' in progress; the 'Architectural Dictionary of the Royal Institute of Architects,' also in progress, in large folio; 'Dictionnaire Raisonné du Mobilier, de l'époque Carlovingienne à la Renaissance,' 8vo, Par. 1858, &c. The first part treating of 'Meubles,' is in 1 vol., and is being followed by other vols. on—2° Ustensiles, Outils, Instruments, &c.; 3° Orfèvriere; 4° Habits, Vêtements, Parure; 5° Armes, Equipements Militaires, Harnais; 6° Bijous. 'A Dictionary of Photography,' by T. Sutton, in 1 vol. 8vo, 1858; 'Dictionary of Botanical Terms;' and Page's 'Dictionary of Terms used in Geology,' &c. &c.

III. *Dictionaries of Things.* This, the third class of dictionaries, includes all the abstract sciences, the mixed or applied sciences, the departments of criticism and the fine arts, and the whole range of metaphysical and moral speculation. It is true that some of these subjects cannot be treated of without a reference to facts; but the facts here are not viewed simply as such, but either as subordinate to principles or as modifying their operation. No very rigorous adherence to the limits of a definition, however, is to be expected in a dictionary of any kind, which must in all cases be a somewhat unsystematic performance, and accordingly we have few, if any, dictionaries which are exclusively dictionaries of things in the sense that has just been explained. Many of the dictionaries referred to under the last head are dictionaries of things as well as of facts: that is to say, they contain, mixed up with their statements of facts, expositions or discussions of principles. On the other hand, dictionaries of things are generally also dictionaries of facts, and sometimes lexicons, or dictionaries of words and phrases, in addition. The most important works of this description have been published under the title of Dictionaries of the Arts and Sciences, or Encyclopædias. By the word *ἐγκυκλοπαιδεία*, encyclopædia, the Greeks seem to have understood the whole circle of learning, or of the liberal arts, or instruction therein, the term being so applied under the notion that all the departments of human knowledge were naturally connected together so as to form a sort of circle or complete system. Pliny ('Nat. Hist.' præf.) speaks of the encyclopædia of the Greeks as an expression for the whole field of knowledge: "Jam omnia attingenda, quæ Græci *τῆς ἐγκυκλοπαιδείας* vocant." Quintilian (i. 10) defines it as the orb or complete circle of human learning: "Orbis illa doctrinæ, quam Græci *ἐγκυκλοπαιδείαν* vocant." Vitruvius (vi. præf.) describes the encyclios or *ἐγκύκλιος παιδεία* of the Greeks as the discipline of all the branches of learning: "doctrinarum omnium disciplina." It does not appear that the term encyclopædia was ever anciently used as meaning a work treating of all the various kinds of knowledge. It has, however, as just observed, become the common title for such works in modern times. Perhaps it was first so applied by some of the Arabian writers of the middle ages, one of whom at least, Alfarabius, who flourished in the 10th century, is stated to have compiled a general treatise on the sciences, still preserved, under this title. Several such treatises with the same title appeared in Europe about the end of the 16th and beginning of the 17th centuries, the most famous of which was that of John Henry Alstedius, which was first published in 2 vols. fol. in 1630. (See preface to Supplement to 'Encyclopædia Britannica,' and Morhoffii Polyhistor, vol. i. lib. ii. chap. 7, for an account of this and other early encyclopædias.) But none of these works were dictionaries: they were merely collections of treatises, rather resembling such works as Dodsley's 'Preceptor' than answering to the modern notion of an encyclopædia. A much nearer resemblance to the modern encyclopædia is presented by the 'Lexicon Universale Historico-Geographico-Chronologico-Poetico-Philologicum' of Joh. Jac. Hofman, first published at Basle, in 2 vols. fol., 1677, and followed by a 'Continuatio' or Supplement, of the same extent, in 1683; or, the two publications incorporated in 4 vols. fol., Lug. Bat., 1698. The form at least of this work has been generally preserved in our more recent encyclopædias and dictionaries of the arts and sciences, although most of these, by including the principles of science as well as facts, have extended their scope somewhat beyond Hofmann's design. His two supplementary volumes, however, embody a great deal of the natural science of his time; and the work altogether contains much curious learning not readily found elsewhere. Although not evidencing any very superior sagacity, penetration, or elegance of scholarship, it is a wonderful performance for an individual, and still remains a most useful book of reference.

The first English "universal dictionary of the arts and sciences" was the 'Lexicon Technicum' of Dr. John Harris, of which the first vol. in fol. appeared at London in 1706, and the second, completing the work, in 1710. It was afterwards extended to three volumes. "With this," says Watt, ('Bibliotheca Britannica'), "originated all the other dictionaries of arts and science and cyclopædias that have since appeared." Harris's Lexicon enjoyed great popularity for a considerable time after its first appearance, as may be inferred from the fact that it passed through five editions in about thirty years; and in the mathematical and physical department especially it is admitted to have been very ably executed. It was not long, however, before it found a rival in Chambers's 'Cyclopædia,' the first edition of which appeared in 2 vols. fol. in 1728. [CHAMBERS, EPHRAIM, in BIOG. DIV.] The professed peculiarity of the new work was, that it proposed to "consider the several matters not only in themselves, but relatively, or as they respect each other; both to treat them as so many wholes, and as so many parts of some greater whole." This was attempted to be done by a system of references from one article to another, so as to connect the subordinate particulars among themselves, and to indicate the great division of knowledge to which each belonged. In this way the work, which, in the seventh edition (1778–85), was extended to 4 vols. fol., contained no complete treatises on any of the sciences, nor other articles of any considerable length. Various other works followed, compiled upon much the same plan, among which were, Barrow's 'New and Universal Dictionary of Arts and Sciences,' in 1 vol. fol., 1751, with a supplemental vol. published in 1754; 'A new and complete Dictionary of Arts and Sciences, by a Society of Gentlemen' (commonly, from the name of the publisher, called Owen's Dictionary), 4 vols., 8vo., 1754; and 'The Complete Dictionary of Arts and Sciences,' in 3 vols. fol., 1766, by the Rev. Henry Croker, Dr. Thomas Williams, and Mr. Samuel Clark.

A work upon a different plan had also appeared in 2 vols. fol. in 1745, by Dr. De Coetlogon, a native of France, naturalised in England, under the title of 'An Universal History of Arts and Sciences, or a Comprehensive Illustration of all Sciences and of all Arts.' This was in fact a dictionary, the subjects being treated in alphabetical order, and Mr. Macvey Napier considers it to have probably suggested the 'Encyclopædia Britannica,' the first edition of which, in 3 vols. 4to., appeared at Edinburgh in 1771. It professed to be compiled "by a Society of Gentlemen in Scotland, upon a new plan, in which the different sciences and arts are digested into distinct treatises or systems." This plan however had been already adopted in Dr. Coetlogon's work. The proprietor and principal compiler of the Edinburgh work was Mr. William Smellie, the printer, a man of much ability and considerable literary attainments. For the subsequent history of the 'Encyclopædia Britannica,' which in the fourth edition, completed in 1810, was extended to 20 vols., and to which a Supplement in 6 vols. was added in 1824, we must refer to Mr. Napier's preface. An eighth edition of the work, in which the Supplement is incorporated, is now in course of publication. Of other English Cyclopædias, we may mention the 'Dictionarium Polygraphicum, or the whole body of Arts regularly digested,' in 2 vols. 8vo, London, 1735; the 'English Cyclopædia, being a Collection of Treatises and a Dictionary of Terms illustrative of the Arts and Sciences,' published by Kearsley, in 10 vols. 4to, 1795-1803; E. A. Kendal's 'Pocket Cyclopædia,' 6 vols. 12mo, 1802; and Hall's 'Dictionary of Arts and Sciences, 3 vols. folio. Two others better deserving of notice were next undertaken: the 'Cyclopædia, or a New Universal Dictionary of Arts and Sciences,' conducted by the late Dr. Rees, and commonly known by his name, although professing to be only a new edition of Chambers, begun in 1802, and completed in 45 vols. 4to, (of which 6 were plates) in 1819; and the 'Edinburgh Cyclopædia,' edited by Dr. (now Sir David) Brewster, begun in 1810, and completed in 36 parts, or 18 vols. 4to, in 1830. The 'Encyclopædia Metropolitana' was begun in 1818, being announced as a Universal Dictionary of Knowledge on an original plan; comprising the twofold advantages of a philosophical and an alphabetical arrangement. This work was completed in 1846, and is arranged in four divisions; the 1st, comprehending the Pure Sciences; the 2nd, the Mixed and Applied Sciences; the 3rd, the Biographical and Historical articles; and the 4th, the Miscellaneous and Lexicographical articles. 'The Penny Cyclopædia of the Society for the Diffusion of Useful Knowledge' was begun in 1833, published regularly in numbers and in volumes, and completed in 1843; two volumes of Supplement were added in 1847; and a second Supplement in one volume in 1858. The articles in this were all compiled from original sources, and the total expense for the literary labour did not fall short of 45,000*l*. The 'National Cyclopædia,' in 12 vols. 8vo, 1847–51, was an abridgment of the 'Penny Cyclopædia.' Of other works of this class, it will be sufficient to mention W. Nicholson's 'British Cyclopædia,' 6 vols. 8vo, 1807-9; Enfield's 'New Encyclopædia,' 10 vols. 12mo, London, 1809–11; Johnson's and Exley's 'Imperial Encyclopædia,' 4 vols. 4to, London, 1809; Wilkes's 'Encyclopædia Londinensis, or General Dictionary of Arts, Sciences, and Literature,' &c., in 24 vols. 4to, London, 1810-29; Amyas Burrowes's 'Modern Encyclopædia, a general Dictionary of Arts, Sciences, and Literature,' 1816; Miller's 'Encyclopædia Edinensis, or Dictionary of Arts, Sciences, and Miscellaneous Literature,' 6 vols. 4to, Edinburgh, 1816; and the 'Encyclopædia Perthensis, intended to supersede the use of other Books of Reference,' in 23 vols. 8vo, Edinburgh, second edition, 1816; the 'Oxford Encylopædia, or Dictionary of Arts, Sciences, and General Literature,' in 6 vols. 4to, Oxford, 1828; the 'London Encyclopædia, or Universal Dictionary of Science, Art, Literature, and Practical Mechanics,' in 22 vols. 8vo, London, 1829; Partington's 'British Cyclopædia,' London, 10 vols. 8vo, 1835-38, in four divisions of Arts and Sciences; Biography; Literature, History, Geography, Law, and Politics; and Natural History; and the 'Cyclopædia of Useful Arts,' by C. Tomlinson, in 2 vols. 8vo, 1852.

Pertaining to English literature, as being in the English language, there are also the 'Encyclopædia Americana, a popular Dictionary of Arts, Sciences, Literature, History, Politics, and Biography,' &c., edited by F. Lieber, assisted by E. Wigglesworth, based on the German 'Conversations-Lexikon,' in 14 vols. 8vo, Philadelphia, 1829-48. The German work is also the base of the 'Popular Encyclopædia, or Conversations Lexicon,' in 7 vols. royal 8vo, published by Blackie of Glasgow in 1841; and the 'American Cyclopædia,' edited by George Ripley and Charles A. Dana, of which only four volumes 4to. have yet (1859) appeared, extending to the word Chartres; in the preface to this work special obligation is acknowledged "to the 'English Encyclopædia,' edited by Mr. Charles Knight, whose well-digested summaries, in some instances, have been drawn upon for useful information." The tenth edition of the original work is also the declared base of Chambers's 'Encyclopædia,' now in course of publication. Dr. Lardner's 'Cyclopædia,' a collection of independent works, bound together by nothing but the title, does not belong to this class of works. The 'English Cyclopædia,' commenced in 1853, "in four divisions, of Geography, Natural History, Biography, and Arts and Sciences," is founded upon the copyright of the 'Penny Cyclopædia;' with large additions and corrections, including a new literary outlay quite in proportion to that branch of expenditure on its predecessor.

Of foreign works of this class, perhaps the earliest was that entitled 'Georgii Vallæ Placentini viri clariss. de expetendis et fugiendis rebus opus.' It was printed in 2 vols. folio, by Aldus, in 1501. It is divided into books, of which there are three on arithmetic; five on music; six on geometry, in which he treats of Euclid, mechanics, optics, &c.; four on astronomy, with observations on the celestial signs as used in medicaments; four on physiology and metaphysics; seven on medicine, with a list of simples; one of problems in physics; four on grammar; three on logic; one on poetry; two on rhetoric; one on moral philosophy; three on domestic and rural economy; one on politics, comprising the pontifical and civil law, the theory of laws in general, and the military art; three on the body, its good and its evil (the first book of the three is on the soul); and one on external things, glory, grandeur, &c. This is a curious work, containing an immense amount of reading, but ill arranged, and adopting many prejudices. The 'Encyclopædia Epistemon, de varii Subjectis,' fol., Basel, 1559. An encyclopædia by J. H. Alstedius, printed at Herborn, in 4to, in 1610; reprinted and enlarged into 4 vols. fol., at Lyon, in 1649. In it he endeavours to prove that the materials and principles of all the arts and sciences are to be found in the Scriptures. Many others followed, among them—by C. Gueinzius, 'Encyclopædia,' 1648, at Halle in Saxony; A. Calovicus, 'Encyclopediæ Disciplinarum realium Ideæ,' Lubec, 1651; J. Apasai, 'Magyar Encyclopædiat,' &c., in the Hungarian language, Utrecht, 1653; J. Magnon, 'La Science Universelle, en vers héroique,' fol., Paris, 1663. This last is part of an encylopædia in verse, which the author intended to have completed in ten volumes, each containing 20,000 verses. Fras. Macedo, 'Encyclopediæ in Agonem Literatorum,' fol., 1677. About this period appeared the two works which may be regarded as the forerunner of subsequent general dictionaries of biography, history, and philosophy. The first of these was the 'Grand Dictionnaire Historique et Critique' of Louis Moreri, of which the first edition was published in 1673, in one vol. folio. With many imperfections the work was of great value, and a second edition was speedily required. This Moreri commenced on a larger scale, but he died before the completion of the second volume. Several editions subsequently appeared under various editors; the last being that of Paris, 1759, in 10 vols. fol. The other work to which we referred, though later in point of date, is of far greater literary importance, and indeed has proved a mine of wealth to succeeding writers, though disfigured by some serious errors of opinion; the 'Dictionnaire Historique et Critique,' of Peter Bayle [BAYLE, in BIOG. DIV.], published at Rotterdam, in 4 vols. fol., in 1697. A more bulky work was that of V. Coronelli, 'Bibliotheca Universalis:' in 1709, nine years before the author's death, 18 folio volumes had appeared, which went no farther than *Cavalieri*. It was to have extended to 45 volumes, folio. Between

1732 and 1747, Zedler's 'Grosses vollstandiges Universal Lexicon aller Wissenschaften und Künste,' &c., was published at Leipzig, in 52 vols. folio. In 1751, appeared in Paris the first volume of the celebrated 'Encyclopédie, or Dictionnaire Raisonné des Sciences, des Arts, et des Métiers,' of Diderot and D'Alembert; the 17th and last of the original series was published in 1765, 11 vols. of plates being added to the text, of which the first was published in 1762, the last in 1772. A Supplement was afterwards added, consisting of four vols. of text and one of plates, fol., 1776-7; and there is besides a 'Table Analytique' of the whole work, compiled by M. Mouchon, in 2 vols. folio, Paris and Amsterdam, 1780. Editions of the work have also been printed in France and other parts of the Continent, both in quarto and octavo. [DIDEROT, in BIOG. DIV.] It has been followed in France by another dictionary of arts and sciences of still greater extent, the 'Encyclopédie Méthodique,' begun in 1782 and finished in 1832, in 201 vols. 4to., including 47 vols. of plates. In this last-mentioned work every art or science is treated of in a separate volume, or series of volumes; so that the whole is in fact merely a collection of dictionaries. Of other foreign encyclopædias, we may notice the German 'Conversations Lexikon' (as it was originally entitled), projected by Mr. Brockhaus, the bookseller of Leipzig, and first published there in 1812. A ninth edition of this work, enlarged to 15 vols. 8vo., was completed in 1848, under its altered title of 'Allgemeine Deutsche Real-Encyclopädie für die gebildeten Stände—Conversations-Lexikon;' and a tenth edition is now (1859) in course of publication. An edition of this work appeared at Leipzig in 1852-58, of which we have already noticed the English translations and appropriations. The French have also issued an 'Encyclopédie des Gens de Monde,' in 22 vols. 8vo., Paris, 1833-44; an 'Encyclopédie Moderne,' with its Supplement, in 36 vols. 8vo, Paris, 1855 57; a 'Dictionnaire de la Conversation et de la Lecture' (edited by W. Duckett), in 68 vols., Paris, 1839-51; of which a new edition, commenced in 1851, is still in progress; and a 'Conversations Lexicon,' founded on the German, now in progress, in 8vo, Paris. There is also now in course of publication the great work conducted by Professors Ersch and Gruber [ERSCH, in BIOG. DIV.], entitled 'Allgemeine Encyclopädie der Wissenschaften und Künste,' which began to be published at Leipzig, in 1818, and of which 122 vols. 4to, have already appeared; namely, the portion from A to Gihom, in 66 vols.; that from H to Junius, in 31 vols; and that from O to Phyxios, in 25 vols. There are other German Cyclopædias; among the most noticeable are Meyer's 'Grosse Conversations Lexikon für die gebildeten Stände,' in 38 vols. royal 8vo, Hildburghausen, 1840-52, with a Supplement in 6 vols., 1853-55, and 8 vols. of plates, consisting of portraits, views, maps, charts, &c.; Pierer's 'Universal Lexikon der Gegenwart und Vergangenheit, oder neuestes encyclopädisches Wörterbuch der Wissenschaften, Künste, und Gewerbe,' third edition, in 34 vols. 8vo., Altenburg, 1840-46. 'Deutsche Enclycopädie; oder, Allgemeines Real-Wörterbuch aller Künste und Wissenschaften.' Von einer Gesellschaft Gelehrten (only carried to letter K), 23 vols. 4to, Frankf. am Mayn, 1778-1807; 'Oesterreichische National-Encyklopädie . . . . vorzüglich der neuern und neuesten Zeit,' 6 vols. 8vo, Wien, 1835-37; being part of a series with 'Oesterreichisches naturhistorisches Bilder-Conversations-Lexikon,' 9 vols. 8vo, Wien, 1835-39; 'Conversations-Lexikon der neuesten Litteratur-Volker und Staatengeschichte,' 2 vols., Leipz. 1841-45: and Herzog's 'Encyclopädie für Protestantische Theologie und Kirche,' to which many eminent German divines have contributed, in 10 vols. 8vo, 1853-9. A translation of a portion of this has also been published in America. In Spanish, there was commenced in 1842 an 'Enciclopedia Española,' in 8vo., published at Madrid, which is still in progress. At Turin, a 'Nuova enciclopedia popolare Italiana,' begun in 4to., in 1856, is also in progress; as is likewise the 'Svenskt Konversations-Lexikon,' in 4 vols. 8vo., Stockholm, 1845-51.

Some account of the encyclopædias in various languages, but neither very clearly nor very accurately drawn up, and mixed with a great deal of superfluous and useless matter, may be found in a little book called 'Nouveau Système Bibliographique mis en usage pour la connaissance des Encyclopédies,' &c., 12mo., Paris, 1821.

DICYANUM. [MELLON.]

DIDYMIUM (Di) is a metal recently discovered in cerite. Cerite eventually yields, by treatment with sulphuric acid, large red crystals, which are sulphate of didymium: when potash is added to a solution of this salt, hydrated oxide of didymium is precipitated; it has a bluish violet colour, and during washing it absorbs carbonic acid from the air, and when dried it consists mostly of carbonate of didymium and is of a light reddish violet colour; by exposure to a red heat the carbonic acid is expelled, and the oxide is obtained in small lumps of a brown or blackish colour; the powder is light brown: if this oxide be exposed to a white heat it assumes a dirty grayish green colour. It has no alkaline reaction, and is dissolved pretty readily even by dilute acids, which yield salts of an amethystine red colour; the latter are not precipitated by sulphide of ammonium unless heated; the oxide is insoluble in carbonate of ammonia.

Before the blowpipe, the oxide mixed with microcosmic salt becomes amethystine red with a tint of violet; when heated with carbonate of soda on platinum foil, it melts into a grayish white mass. It does not appear to have been reduced to the metallic state.

DIELECTRIC. A term applied to a substance through or across which the electric force is acting. [ELECTRICITY.]

DIE-SINKING. In the preparation of coined money and of medals, the most important feature is the engraving of the die which is to form the stamp. The piece of steel is prepared with the utmost care, and is brought to a soft state when about to be submitted to the hands of the engraver. If the die or stamp be for a medal such as those which have been executed at the Mint by Pistrucci and Wyon, and of which the relief is great, the metal requires to be cut away to a greater depth than in the dies intended for the coining of money, such as shillings, &c. By very minute touches, and by the aid of small, fine, hardened steel tools, the engraver cuts away the steel until he has produced, in cavity or "intaglio," an exact reverse of the design for the medal or coin. The steel, in a soft state while being engraved, requires hardening before being applied to use. The face of the die is covered with a protecting layer of pounded charcoal mixed with oil, and the die is then placed face downwards in a crucible, where it is surrounded with pounded charcoal; after being heated to a cherry-red temperature, it is taken out by means of tongs, and plunged into cold water, the sudden action of which renders the steel extremely hard. When further prepared, so as to be rendered more durable, it obtains the name of the *matrix*, and might be used in that state to stamp coins or medals; but as such a matrix is very costly, and might be spoiled by fracture, arrangements are made for producing multiplied copies of it. A small block of soft steel is, by immense pressure, made to receive an impress, *in relief*, from this matrix; and from this second piece, which obtains the name of the *puncheon*, after being hardened and re-touched by the graver, *dies* or duplications of the original matrix are produced. These dies, when intended for coinage, are intrusted to the Clerk of the Irons at the Mint, whose duty it is to superintend the die-press rooms, the purchasing and forging of the steel, and the engraving and hardening of the dies; to receive and transmit all orders respecting the dies; to be present whenever the die-press is used for multiplying the dies; and to exercise general control over all matters relating to them.

In the use of dies by means of the stamping-press, the number of blows required to transfer the device to a blank piece of metal depends upon the depth of the intaglio. Professor Brande states, that in a medal executed by Mr. Wyon, for the Royal Naval College, there was a representation of the head of William IV., in such bold relief as to require thirty blows of a very powerful press to complete the impression; and that it was necessary, on account of the hardening produced by the pressure, to anneal each medal after every third blow; so that every medal was placed in the furnace ten times during the process of stamping. In another instance (a large medal struck by Boulton), some of the copies are said to have received three hundred blows each, and to have required heating and annealing after each blow.

A remarkable method is sometimes adopted of producing medals from a die by means of stamping, but upon metal which is in a semi-liquid instead of a cold and solid state: the method is called *en cliché*, and has been much practised in France. The metal of which these medals are formed is one of the various kinds of fusible metal, such as will melt at a low temperature. Type-metal, consisting of five parts of lead to one of antimony, will answer for the purpose, but it is deemed better when a little more lead is added to it; many different alloys of tin, lead, bismuth, and antimony, however, will suffice. The die to be employed is fixed face downward at the lower end of a stamper, which works within a box or case to prevent the liquid metal from splashing about; at the bottom of the box is a cast-iron plate, on which is placed a small paper tray. The alloy is melted, and allowed to cool down to a pasty state; a little of it is placed in the paper tray; the box is closed on all sides, and the stamper is allowed to fall on the alloy, by which a medallion is produced from the die, rough at the edges, and with an impress only on one side. The contact of the cold die solidifies the alloy, and produces a clear and tolerably sharp impression. The medallions so produced are trimmed at the edge by a lathe, and rendered smooth at the back; sometimes two are fixed together back to back, to form a perfect medallion; and sometimes they are mounted in cases, with only one side visible—the surface being bronzed with metallic sulphates. In some instances, instead of cliché medals being produced from engraved dies, cliché moulds are produced from models made of plaster, wood, sulphur, clay, wax, or metal: thus, the Italian figure-casters often make casts from medallions and small bassi-rilievi by means of moulds which have been made *en cliché* from models.

Die-sinking is regarded in the above paragraphs chiefly in its connection with the fine arts; but the slightest glance at the industry of Birmingham, and other seats of the metal manufacture, will show how largely die-sinking is necessary for the operations carried on in the stamping-works. In this point of view, a suggestion worthy of notice was made by Mr. Kidd, of Sheffield, and communicated to the 'Mechanics' Magazine' in 1858. It was to the effect that die-sinking might possibly be accomplished by the aid of electro-metallurgy. "Take, as an example," he said, "a pair of dies for casting metal buttons. Let a model in wax be made, with the face of the button standing out in relief on a flat surface of (say) an inch all round its edge. The face of the model must now have a conducting surface imparted to it, either by black-lead or by the phosphorus and gold solution. Then place it in an electrotyping apparatus for receiving a coating of iron. When this coating is of tolerable thickness (say one-

[illegible] of an inch, a piece of iron, of the same diameter as the model, and perhaps half an inch thick, is to be covered with wax on the back and circumference, and placed with the face perfectly free from grease or dust opposite to the model, and touching the iron on [illegible]. The deposited metal of the galvanic trough, will now be thrown down between the two, and if the strength of the battery be carefully regulated, they will be united into one whole piece. All the wax may now be removed, and the edges trimmed with a file. We shall thus have one of the dies in which to cast the button; the other may be made in the same manner. This method is applicable to the making of dies for casting all kinds of ornaments in soft metal, such as teapot-knobs, handles and feet of cruet-frames; also dies for stamping soft materials, as leather shot pouches, bookbinders' work, &c. As the temper of the metal deposited depends entirely upon the intensity of the battery-current, I have no doubt that, if this were carefully regulated, dies might be made fit for stamping Britannia metal or copper. The great recommendation of the process is its extreme cheapness."

DI'ESIS, in ancient music (*δίεσις, division*). The Greeks divided a tone into a major and minor semitone; the greater was called an apotome [APOTOME], the lesser a limma, or Diesis: to the difference between the two the name of comma [COMMA] was given. But it must here, once for all, be observed, that the Greek writers, if we really enter into their meaning, differ much in their definitions of musical inetrvals, and that the moderns are no less at variance in their interpretation of many ancient terms of the art.

DIETHYLAMINE. [ORGANIC BASES.]

DIETHYLANCYLAMINE. [ORGANIC BASES.]

DIETHYLANILINE. Synonymous with *diethylphenylamine*. [ANILINE.]

DIETHYLCHLORANILINE ($N(C_{12}H_4Cl(C_4H_5)_2)$. A derivative from chloraniline. [ANILINE.]

DIETHYLCONINE ($C_{22}H_{23}N$). An organic base formed by replacing two equivalents of hydrogen in conine by two of ethyl. [CONINE.]

DIETHYL-CYANAMIDE $\left(N\begin{cases}C_4H_5\\C_4H_5\\Cy\end{cases}\right)$. An organic body consisting of cyanamide in which two equivalents of hydrogen are replaced by two of the radical ethyl. [CYANAMIDE.]

DIETHYLCYANURIC ACID ($C_{14}H_{10}N_3O_6, HO$). A crystalline acid, obtained as a secondary product in the preparation of cyanuric ether. Fused with potash it yields ethylamine.

DIETHYLINE ($C_{14}H_{16}O_6$). This organic compound is formed by the juxtaposition of one atom of glycerine with two atoms of alcohol, and the abstraction of four atoms of water.

$$\underbrace{C_6H_8O_6}_{\text{Glycerine.}} + \underbrace{2C_4H_6O_2}_{\text{Alcohol.}} - 4HO = \underbrace{C_{14}H_{16}O_6}_{\text{Diethyline.}}$$

It is prepared by heating a mixture of glycerine, bromide of ethyl, and potash to 212° Fahr. for about 80 hours, then separating the upper layer of resulting liquid from the lower, and distilling the former. That portion of the distillate which passes at 376° Fahr. is pure diethyline. This body is a colourless and transparent liquid, possessing a slight ethereal odour and a specific gravity of ·92. It is but slightly soluble in water. Heated with quicklime it disengages acrolein.

DIETHYLMECONIC ACID. [MECONIC ACID.]

DIETHYLOXAMIDE. [OXAMIDE.]

DIETHYLPHENYLAMINE. [ANILINE.]

DIETHYLPHOSPHORIC ACID. [PHOSPHORIC ACID.]

DIETHYL-TOLUIDINE. [TOLUIDINE.]

DIETHYL-UREA. [UREA.]

DIET. [FOOD.]

DIFFARREATION. [MARRIAGE.]

DIFFERENCE, the excess of one quantity over another. This fundamental meaning of the term is almost lost in the higher parts of mathematics, from the association of it with a methodised theory, derived from the consideration of the differences presented by successive quantities which follow a regular law. It is, therefore, a very wide branch of pure mathematics which must be considered under this term; namely, the method of calculus of differences. And the connection of this subject with the differential calculus (the results of the latter being, in one point of view, particular cases of the former) renders it impossible to treat of the two with that perfect separation which the alphabetical arrangement of a work like the present requires. Following the plan which we have laid down in other articles, we shall here describe the most important results connected with the term in question, referring for information on other matters to the following articles: INTEGRATION, FINITE; GENERATING FUNCTIONS, THEORY OF; EXPONENTS, NOTATION OF; OPERATION; EQUATIONS OF DIFFERENCES; INTERPOLATION.

If we carry the hand along a sheet of paper, laying down points with a pen at various intervals, we get a number of points, through which an infinite number of curves may be made to pass; but, generally speaking, there is one which is more simple than all the rest. If we also assign various numbers, we may conceive them all to be values of some function of a variable x, answering to $x=1$, $x=2$, &c. Thus we may ask the following question: what is that function of x of which 43, 47, 53, 61, 71, 83, &c., are the values, when x is successively made equal to 1, 2, 3, 4, 5, 6, &c.? This problem is indeterminate, with respect to common algebra merely, unless we can ascertain a law by which the series can be continued *ad infinitum*, and which it is allowable to assume; it then becomes determinate with respect to the expressions of common algebra only, but is again indeterminate if we are allowed to assume the transcendental expressions of trigonometry or the integral calculus. Confining ourselves to the expressions of common algebra, we may detect any law which prevails throughout the whole series by taking the difference between each term and the next, and thus forming a new series; and then by repeating this process again and again until the series so formed presents an easily perceptible law. Thus in the preceding case we have

$$\begin{array}{llllllll}
 & \text{Given series} & 43 & 47 & 53 & 61 & 71 & 83\ \dots \\
\text{Series of} \left\{\begin{array}{l}\\ \\ \end{array}\right. & \text{First differences} & 4 & 6 & 8 & 10 & 12 & \\
 & \text{Second differences} & & 2 & 2 & 2 & 2 &
\end{array}$$

We now see that, irregular as the first series may appear, the successive differences of the successive differences of its terms are always the same, and we may thus extend the series further. Thus we have—

$$\begin{array}{cccccc}
83 & 97 & 113 & 131 & 151 & 173,\ \&c. \\
12 & 14 & 16 & 18 & 20 & 22,\ \&c. \\
2 & 2 & 2 & 2 & 2 & 2,\ \&c.
\end{array}$$

But still this question remains, assuming the preceding law of continuation, and also that we have thus the values of some function of x answering to $x=1$ (namely, 43), $x=2$ (47), &c.: What is the value of the function answering to fractional values of x; for instance, when $x=2\frac{1}{2}$? Considering that $x=2$ gives 97, and $x=3$ gives 113, it might seem at first sight that $x=2\frac{1}{2}$ should give 105. But a moment's consideration will show that this can only be in the series

$$81 \quad 97 \quad 113 \quad 129,\ \&c.,$$

and that the irregularity of the progression from term to term will require a law to express it, such as will not allow of uniform progression between the terms. Such are the notions which might be made to suggest themselves, and the difficulties of which find their answers in the mathematical consideration of the subject.

Let any term chosen at pleasure in a series be called a, let the next term be a_1, the next a_2, and so on: that is, a_n means the nth term from a, not reckoning a. The succession of *first differences* (a more convenient way of expressing the *first succession* of differences) is—

$$a_1-a,\ a_2-a_1,\ a_3-a_2,\ a_4-a_3\ \dots\dots$$

The succession of *second differences* (*second succession* of differences) is—

$$a_2-a_1-(a_1-a),\ \text{or}\ a_2-2a_1+a$$
$$a_3-a_2-(a_2-a_1),\ \text{or}\ a_3-2a_2+a_1,\ \&c.$$

The succession of third differences, similarly derived from the preceding, is—

$$a_3-3a_2+3a_1-a,$$
$$a_4-3a_3+3a_2-a_1,\ \&c.$$

From which it may be made evident to any one who knows the binomial theorem and the law of its co-efficients, that the first term of the nth succession of differences is—

$$a_n-n\,a_{n-1}+n\,\frac{n-1}{2}\,a_{n-2}-\ \dots\ (n+1\ \text{terms}).$$

It is usual to denote this by $\Delta^n a$, the letter Δ standing for the operation of taking the difference, the exponent expressing that this operation has been repeated until it has been performed n times, and a being the term of the series used in the first operation. The symbol is called the nth difference of a.

If, then, we write the series and its successions of differences, not using the results of the operation, but their symbols, we have as follows:—

$$\begin{array}{cccccc}
a & a_1 & a_2 & a_3 & a_4 & \dots\dots \\
\Delta a & \Delta a_1 & \Delta a_2 & \Delta a_3 & & \dots\dots\dots \\
\Delta^2 a & \Delta^2 a_1 & \Delta^2 a_2 & & \dots\dots & \\
\Delta^3 a & \Delta^3 a_1 & & \dots\dots & & \\
\&c. & & & & &
\end{array}$$

From which we find that $a_1=a+\Delta a$.

$$\begin{aligned}
a_2 &= a_1+\Delta a_1 = a+\Delta a+(\Delta a+\Delta^2 a) \\
&= a+2\Delta a+\Delta^2 a \\
a_3 &= a_1+2\Delta a_1+\Delta^2 a_1 = a+\Delta a \\
&\qquad +2(\Delta a+\Delta^2 a) \\
&\qquad +\Delta^2 a+\Delta^3 a
\end{aligned}$$

$$\text{or, } a_3=a+3\Delta a+3a\,\Delta^2 a+\Delta^3 a.$$

Proceeding in this manner, and by the assistance of the binomial theorem as before, we find that—

$$a_n=a+n\,\Delta a+n\,\frac{n-1}{2}\,\Delta^2 a+\ \dots\ (n+1\ \text{terms}).$$

These two theorems are the fundamental parts of the whole theory of differences; and our limits will not allow us to go further into the subject. We shall only observe, that it is most desirable that this very elementary branch of pure mathematics should be taught as a part of common algebra, or at least with the first rudiments of the differential calculus. The almost universal practice of deferring this subject until the student is master of the integral calculus, is entirely subversive of all natural order, and is perhaps one of the reasons why the differential calculus is proverbially difficult. Various developments and applications are to be found in every work on the subject.

The term difference is Continental; the older English term was *increment.*

DIFFERENCE, ASCENSIONAL. [Ascension.]

DIFFERENCE, EQUATIONS OF. [Equations of Differences.]

DIFFERENTIAL CALCULUS, the name given by Leibnitz to the science which was digested nearly about the same time by himself and Newton, independently of each other [Fluxions; Commercium Epistolicum], and which has of late years almost exclusively prevailed in this country, to the exclusion of the name, notation, and (so far as they differ) methods of Newton's fluxions.

It is impossible, in the smallest degree, to exhibit the present state and uses of a science into which all others merge as the student approaches the higher applications of mathematics. The article Differential Coefficient will, so far as it goes, give some idea of the nature of its first step; but the following remarks must be considered as intended for the student who has made some progress in a modern elementary work.

The history of the differential calculus, at its first rise, is so connected with that of the Newtonian Fluxions, in consequence of the celebrated dispute as to the right of invention, that we have thought it best to refer the whole point to the last-named article. On the history of the science since the time of Newton, there is no work from which we can trace out a connected account of the various steps by which the present system has been formed. In fact, most of the new investigations have been made with reference to some particular points of physical science. It would be very difficult to write the history of this calculus without entering at the same time into that of mechanics, optics, astronomy, &c. &c., and of every subject to which it has ever been applied. An attempt at the former without the latter would be an account of the progress of language without mention of literature, oratory, or the drama.

In the meanwhile, seeing that notions as to the most proper and useful basis on which to build this science are far from being fixed, the most advantageous course which we can here adopt is to give a short account of the various systems which have been proposed, referring to such articles and treatises as will enable the student to obtain further information. These different systems all produce the same results, expressed in very similar manners; there is no question between them as to the truth or falsehood of any one deduction, and a practised intellect can always see how the principles of any one, *assumed as granted,* may be made to furnish demonstrations of those of any other. It is therefore, with some exception, a psychological rather than a mathematical difference which agitates (or rather which did agitate) the mathematical world. We do not mean to say that opinions are now agreed; but it seems that the question is left open, it being admitted that the manner in which a student arrives at his knowledge of the subject in the first instance is not of the greatest importance, provided that, when it has been obtained, he give his attention to the comparison of the various methods by which he might have attained the same end.

The precursors of Newton and Leibnitz, namely, Archimedes, Cavalieri, Wallis, Barrow, Fermat, Roberval, and others, touched so near upon the differential calculus, that it is obvious any one of them might have taken the place of either of the first, if he had possessed more powerful means of algebraical development. After Vieta, Descartes, Wallis, and Newton (considered only as the discoverer of the binomial theorem), the step to a formal calculus was comparatively small. The essential part of the difficulty had been removed, and by much the greater part of the distance between Archimedes and Leibnitz had been gained. This point once attained, *methods* sprung up with rapidity, and in little more than a century we find the introduction of the various schemes which it will be necessary to mention, namely—Leibnitz's method of infinitesimals; Newton's method of prime and ultimate ratios; Newton's method of fluxions; Landen's method of vanishing fractions, or residual analysis; D'Alembert's method of limits; Lagrange's method of derivation. In saying, however, that the step to a formal calculus made by Newton and Leibnitz was comparatively small, we only mean that it appears small to those who have been taught how to make it. For one man who can make this *last simple step*, which puts the many into the position formerly held by the few, there are scores who can *all but* do it, and who have claims put in for them when the thing is done, but not before. A proverb, it is said, is the wisdom of many, but the wit of one; a great method in science is always within the perception of many, before it is within the grasp of one.

Many other forms have been proposed, which either coincide in principle with one or other of the preceding, or are without any independent claim to notice. Several of the preceding, indeed, are more distinguished from each other by historical notoriety than by essential difference of character. If we distinguish carefully between the first principles of a method and the manner in which those principles are applied to algebra, it would not be any great stretch of assertion to contend that all the methods except the last are different ways of expressing the same fundamental ideas; and that the last (Lagrange's) is a proof that, so long as the preceding methods employed the usual amount of algebraical assumption in the establishment of the connection between themselves and algebra, that same quantity of assumption would have been sufficient for the basis of a purely algebraical science, equivalent to the differential calculus.

The method of Leibnitz assumes that quantities are made up of infinite numbers of infinitely small parts. [Infinitesimal Calculus; Infinite.] It is a sort of atomic theory of pure magnitude, which is most obviously either false or obscure; for so far as infinitely small quantities can be definitely explained as objective realities, it is obvious that there are no such things; and any obscurity left in their definition extends itself throughout the whole science. But the falsehood of the supposition is not absolute; for though magnitudes cannot be distinctly laid down to be composed of an *infinite* number of *infinitely small* parts, yet any magnitude can be divided into a number of parts *greater than any we may happen to name,* each of which parts shall be *less than any magnitude we may happen to name.* Thus it is perfectly obvious that a foot may be divided into parts more than a million in number, each of which shall be less than the hundred millionth part of an inch. If we may use such a phrase, the falsehood of the assertion may be made of as small an intensity as we please, and the consequence is, that its results turn out absolutely correct. All the difficulties of the science are concentrated into one single assertion; and when this assertion is once fairly understood and received in a correct sense, all that follows is more easily understood and remembered, and far more easily applied, than the results of any other method. Whichever of the systems a student pursues, it is our decided opinion that he should accustom himself to translate every result into the language of the infinitesimal calculus, and endeavour to demonstrate it by the methods of the same. It is usual to give a chapter on this method in elementary works; in addition to which we should strongly recommend to the student of principles, Carnot, 'Réflexions sur la Metaphysique du Calcul Infinitesimal,' last edition, Paris, 1839. But we must be understood not to recommend the peculiar method of explaining the difficulties of infinitesimals adopted in this work, but only the manner of stating the points of difficulty, and the comparison of the different systems.

The system of Newton, known by the name of prime and ultimate ratios, was set forth in the first section of the Principia, and is the method pursued throughout that work. It is in reality a method of limits, exhibited in a form which allows of a more ready application to geometry than to algebra, and accordingly it is abandoned by Newton himself in the method of fluxions. Instead of considering and comparing simultaneous increments of infinitely small magnitude, the ratios of small but finite increments are taken; and not these exactly, but the limits towards which they approach when the increments are diminished, which are called *ultimate* ratios, or *nascent* ratios, according as the increments are supposed to be *in the act* of growing from or diminishing towards nothing. The expression of Newton will justify us in using the three words in italics: "Objectio est, quod quantitatum evanescentium nulla sit ultima proportio: quippe quæ, antequam evanuerunt, non est ultima; ubi evanuerunt, nulla est. . . . . Similiter per ultimam rationem quantitatum evanescentium, intellegendam esse rationem quantitatum, *non antequam evanescunt, non postea, sed quâcum evanescunt.* Pariter et ratio prima nascentium est ratio quâcum nascuntur?" The student must seek for the account of this method in the first section of the Principia already cited, and in the article Ratios, Prime and Ultimate. It may be observed that in illustrating the preceding answer, Newton appeals to the fundamental considerations on which his other method (if it be really another method) is founded, to which we now come.

The method of fluxions was also given by Newton, and with a peculiar notation, which maintained its ground in this country until about the year 1816. [Fluxions.] It will be seen in the articles Direction, Velocity, Force, &c., that there are many fundamental ideas, connected with sensible objects, which lead to a practical differential calculus, and might have happened to have been the means of suggesting a strict and mathematical theory. Newton adopted one of these, that of velocity, of which it may be said that its assumption as an answer to objections is an evasion of all the metaphysical difficulties of the subject. Since the proportions of all quantities may be represented by those of straight lines, the nature of the comparative changes which take place in continuously increasing or decreasing quantities may be referred to the velocities with which the terminal points of straight lines change their places. Velocity once clearly defined, in cases where it is variable, there is no further difficulty; but unfortunately a distinct conception of the measure of velocity is precisely equivalent to finding a meaning for the differential or fluxional coefficient independently of it. The theory of fluxions is best exhibited in the work of Maclaurin, 'Treatise on Fluxions,' 2 vols. 4to., Edinburgh, 1742, which, for rigorous and consistent application of its own principles, has, in our opinion, never been surpassed. It has the advantage of having been written in answer to acute objections of principle [Berkeley], and i *the* work on fluxions.

The method of limits of D'Alembert, which is now more frequently used than any other, was considered by the author himself as an explanation of Newton's prime and ultimate ratios. It is usual to attribute the exposition of this method to D'Alembert (and, considered as an actual application of limits, correctly), though several, previously to him, had made special applications of the principle. The articles in the Encyclopédie must be considered as the *pièces justificatives.* The following article, DIFFERENTIAL COEFFICIENT, will explain this method, which contains the point in which the principles of all the preceding unite, and which must more or less be in all. See also the article LIMIT.

The two remaining methods (those of Landen and Lagrange) are attempts to establish the science upon purely algebraical principles. Previously to entering upon them, we must remark that none of the preceding theorists attempted to make his system furnish any additional security to the methods of the algebra already in use. Such as it was, correct or incorrect, clear or obscure, no one gave a moment's consideration to the fact that algebra already contained difficulties of precisely the same character as those which were matter of dispute in the differential calculus. Taking it for granted that algebra in every part stood already upon as firm a basis as the differential calculus could ever on any supposition be expected to do, it was a matter of some interest to make the latter a pure extension of the former.

The residual analysis of Landen is a technically algebraical exhibition of the theory of prime and ultimate ratios. The tract in which it was promulgated, 'the Residual Analysis, a new branch of the Algebraic Art,' &c., appeared in 1764. When it is considered that this new branch of the algebraic art was only old fluxions in a different dress, the title may excite surprise, if we remember how well Landen deserved his reputation. But it must be remembered that all the discussion of which this article is meant to elucidate the history, arose from a tendency to consider two methods as *mathematically* different, which were not the same in the method of enunciating their first principles. A something between Landen and D'Alembert, as to principle, published in 1748, was called the 'Doctrine of Ultimators, containing a new Acquisition, &c., or a Discovery of the true and genuine Foundation of what has hitherto mistakenly prevailed under the improper names of Fluxions and the Differential Calculus.' The difference between Landen and Newton will appear in the article FRACTIONS, VANISHING, and in the instances which we shall presently give. It is the LIMIT of D'Alembert supposed to be *attained*, instead of being a *terminus* which can be attained as nearly as we please. A little difference of algebraical suppositions makes a fallacious difference of form; and though the residual analysis draws less upon the disputable part of algebra than the method of Lagrange, the sole reason of this is that the former does not go so far into the subject as the latter.

The method of Lagrange, first given in the public lectures at the École Normale, and afterwards published separately under the title of *Théorie des Fonctions*, is a deduction of the whole science from Taylor's Theorem, which being absolutely granted, undoubtedly all the rest may be made to follow. If $\phi\,(x+h)$ can be always expanded in a form of which the two first terms are $\phi x+\phi' x.h$, and if $\phi'\,(x+h)$ be related in the same manner to $\phi' x+\phi'' x.h$, and $\phi''(x+h)$ to $\phi'' x+\phi''' x.h$, and so on, it can be made to follow that

$$\phi\,(x+h)=\phi x+\phi' x.h+\phi'' x.\frac{h^2}{2}+\phi''' x.\frac{h^3}{2.3}+\&c.$$

upon principles as sound as those of algebra in the hands of Maclaurin, or Euler, or Clairaut, as elementary writers. It is our opinion that Lagrange has not been correctly understood, nor fairly dealt with, by those who have compared his theory of functions with the other methods. Undoubtedly any one who should maintain the unqualified admissibility of Lagrange's work must assert both the major and minor of the following syllogism.

Algebraical expansion (*théories des suites* is Lagrange's phrase) as generally received in 1790, was founded on sound principles: the *théorie des fonctions* is a logical and incontestable result of such algebra; therefore, &c.

All the attacks upon Lagrange have denied the major of this syllogism, whereas it appears to us that he never intended to assert more than the minor. Perceiving that the mathematical world was in the habit of calling in the aid of limits or infinitesimals, to help a *certain algebra* in deducing certain conclusions, he showed them how that very algebra, good or bad, was competent to the deduction of the same conclusions without either limits or infinitesimals; and he was correct. Notwithstanding anything in the work in question, Lagrange might have admitted all that we shall find it necessary to say against his system, absolutely considered, in the article FUNCTIONS, THEORY OF.

A new question has arisen of late years, namely, whether the theory of limits be not absolutely necessary to the rigorous development of common algebraical forms, and whether this same theory of limits may not be applied to the establishment of the differential calculus, independently of any expansion. A tract of M. Ampère (as we believe), entitled 'Précis du Calcul Differentiel,' &c., is the earliest writing we are acquainted with in which this is attempted to be done. Mr. de Morgan's treatise on the subject, published by the Society for the Diffusion of Useful Knowledge, professes to have the same end in view. The works of M. Cauchy have much in them by which this object is promoted, but expansion is avowedly introduced.

We shall now state two propositions, one geometrical, the other algebraical, in the words of the several systems.

1. *Infinitesimals.*—An infinitely small arc of a circle is equal to its chord.

Prime and Ultimate Ratios.—If an arc of a circle diminish, the ultimate ratio which it bears to its chord is one of equality; or if it begin to increase from nothing, the prime or nascent ratio of the arc and chord is that of equality. Or the arc is *ultimately* equal to its chord.

Fluxions.—If an arc increase from nothing with a uniform velocity, the velocity with which the chord increases is, at the first moment, equal to that of the arc.

Limits.—If the arc of a circle (and therefore its chord) diminish without limit, the limit of the ratio of the arc to the chord is one of equality.

Residual Analysis.—When the arc of a circle $=0\ \frac{\text{arc}}{\text{chord}}=\frac{0}{0}=1$, which is ascertained by clearing the numerator and denominator of a factor which vanishes when arc $=0$.

Theory of Functions.—When the arc is expanded in the following series,

$$\text{Arc} = \text{A} \times \text{chord} + \text{B} \times (\text{chord})^2 + \&c.$$

then A = 1.

2. *Infinitesimals.*—If an infinitely small increment dx be given to x, then x^3 receives the infinitely small increment $3x^2dx$.

Prime and Ultimate Ratios.—The ratio which any increment given to x bears to the consequent increment of x^3 is ultimately that of 1 to $3\,x^2$.

Fluxions.—If x be a line which increases with a velocity $\dot{x}$, then x^3 increases with the velocity $3\,x^2\dot{x}$.

Limits.—The limit of the ratio obtained by dividing an increment of x^3 by the increment of x which produced it, on the supposition that the latter increment diminishes without limit, is $3\,x^2$.

Residual Analysis.—Since

$$\frac{y^3-x^3}{y-x}=x^2+xy+y^2$$

it follows that when $y=x$, $\frac{x^3-x^3}{x-x}=3\,x^2$.

Theory of Functions.—If $(x+h)^3$ be expanded in a series of powers of h, the coefficient of the first power of h is $3x^2$.

DIFFERENTIAL COEFFICIENT. The expressions to which this term is applied are of a degree of importance in the science to which they belong, as great as that of the letters of the alphabet in writing. Without entering into the method of using them, which would be in effect to write a treatise on the differential calculus, we shall make some remarks on the manner of defining and understanding the term.

When two magnitudes are so related that either being given the other is also given, it follows that any change being made in the one, the consequent change in the value of the other can be found, and the two changes can be compared as to magnitude. By this means a rough notion can be formed as to the effect which a change of value in one produces in the other. In such articles as CURVATURE, DIRECTION, VELOCITY, FORCE, &c., it is sufficiently shown that this rough notion, obtained by making a sensible change in one magnitude and comparing it with that produced in another, though sufficient for practical purposes, does not afford any exact and mathematical measure of the thing sought for. In each of the articles cited, it is found necessary to diminish the change originally supposed without limit, and it is not the actual ratio of two changes which we have to consider, but the limit to which that ratio approximates as the changes are diminished without limit. We must distinctly refer the student to sensible objects for an illustration of the cause why it is convenient, and even necessary, to have recourse to the *limit of a ratio.* [See also LIMIT, RATIOS (PRIME AND ULTIMATE), and various articles cited in DIFFERENTIAL CALCULUS.]

Let ϕx be a function of x, called y, which when x is changed into $x+h$, becomes $y+k$, so that

$$k = \phi\,(x+h) - \phi x.$$

Divide k by h, ascertain the limit towards which this quotient approximates when h is diminished without limit, and that limit is what is called the differential coefficient of y with respect to x. For instance, let $y = x^2 + x$; then

$$\begin{aligned} k &= (x+h)^2 + (x+h) - (x^2+x) \\ &= 2\,xh + h^2 + h; \end{aligned}$$

and k divided by h gives $2x + h + 1$, which, when h is diminished without limit, has for the limit of its decrease, $2x + 1$, which is therefore the differential coefficient of $x^2 + x$ with respect to x.

The term *differential coefficient* arises thus. The method of Leibnitz [INFINITESIMAL CALCULUS] proceeds as follows: Imagine x in the preceding expression to be increased by an *infinitely small quantity* (see article just cited for remarks on this phrase) which call dx, the *differential* of x. Then the resulting differential of y is

$$\begin{aligned} dy &= (x + dx)^2 + (x + dx) - (x^2 + x) \\ &= (2x + 1)\, dx + (dx)^2 \end{aligned}$$

Now $(dx)^2$ is rejected as being an infinitely small part of the preceding term, so that $(2x + 1)\, dx$ is the *differential* of $x^2 + x$. The expression $2x + 1$ (which is our preceding result) is here the *coefficient* of the *differential* dx, and when a less objectionable method of obtaining it came into use, still retained the name of differential coefficient. It were exceedingly to be wished that some shorter term could be agreed on for the expression of a result which is so often required to be named.

In the method of Leibnitz the differential coefficient is actually dy divided by dx, and it is still expressed by $\frac{dy}{dx}$ in the more modern methods. But this notation must now be supposed to be obtained as follows: Let the change of x into $x + \Delta x$ be accompanied by that of y into $y + \Delta y$; then $\frac{\Delta y}{\Delta x}$ expresses the algebraical ratio of the change of y to the change of x. In making the convention that $\frac{dy}{dx}$ is to stand for the limit of $\frac{\Delta y}{\Delta x}$, obtained from the supposition that Δx diminishes without limit, we consider the first symbol, not as that of an algebraical fraction, but as one whose *whole* has a meaning, the *parts* having none. This is the case with all *simple* symbols, as distinguished from *compound* symbols: thus in the figure V, standing for five, the two sides of the letter have no independent meaning; while in 4 + 7, each of the three symbols, 4, +, and 7, has meaning contributing to that of the whole, and at the same time independent of it. Thus though we consider $\frac{dy}{dx}$ as pointing out that it is y which has been differentiated, and with respect to x, we do not, in this symbol, assign to dy and dx any independent share of meaning.

The advantage of the notation in question is the connection which it preserves between the practical use of the method of Leibnitz, and the theoretical accuracy of that of limits. For instance, it is strictly true, according to our conventions, that

$$\text{when } y = x^2 + x,\ \frac{dy}{dx} = 2x + 1.$$

but, giving dy and dx separate meaning, it is *not* true that $dy = (2x + 1)\, dx$. Yet the latter equation, though never true, is of this kind, that it may be made as near to truth as we please, if dx may be made as small as we please. For the reason why it cannot therefore be said to be true in the case where $dx = 0$, see Fractions, Vanishing.

The differential coefficient of a differential coefficient is called the *second* differential coefficient; a repetition of the process gives the third differential coefficient: and so on. These, if the original method of notation were proceeded with, should be represented by

$$\frac{dy}{dx} \qquad \frac{d\left(\frac{dy}{dx}\right)}{dx} \qquad \frac{d\left(\frac{d\left(\frac{dy}{dx}\right)}{dx}\right)}{dx}, \text{ \&c.}$$

but a more convenient notation is derived as follows: Let the substitution of $x + \Delta x$ for x take place any number of times in succession, giving

$$\phi(x)\ ,\ \phi(x + \Delta x)\ ,\ \phi(x + 2\Delta x)\ ,\ \phi(x + 3\Delta x), \text{ \&c.}$$

Form the successive differences of the first term [Difference] ϕx or y: then the following theorem can be proved. The nth difference of y, or $\Delta^n y$, divided by the nth power of Δx, or $(\Delta x)^n$, is an expression of which the limit, made by diminishing Δx without limit, gives the same result as arises from differentiating y, n times in succession. We may therefore (subject to the remarks already made on the *first* coefficient) represent the limit of $\frac{\Delta^n y}{(\Delta x)^n}$, by $\frac{d^n y}{(dx)^n}$, so that the function y and its successive differential coefficients are denoted as follows:—

$$y\ ,\ \frac{dy}{dx}\ ,\ \frac{d^2 y}{dx^2}\ ,\ \frac{d^3 y}{dx^3}\ ,\ \frac{d^4 y}{dx^4}\ , \text{ \&c.}$$

It is usual to omit the brackets in the denominators.

DIFFERENTIAL EQUATIONS. [Equations, Differential.]

DIFFERENTIAL THERMOMETER. [Thermometer, Differential.]

DIFFRACTION OF LIGHT. The peculiar modifications which light undergoes when it passes by the edge of an opaque body are classed as phenomena of the *diffraction* or *inflexion* of light.

When a pencil of solar light is admitted into a darkened room through a very small hole in a card, or is collected in a point by means of a convex lens of short focus, and then diverges from that point, if a small opaque plate of any outline be interposed in the course of the ray, the shadow of this object received on a parallel screen behind will be encompassed by a series of coloured bands or fringes of a similar outline with the body, except at its angular points; the order of the colours in each fringe, reckoning from the outside towards the shadow, or inside, is, as in the prismatic spectrum, from red to blue, but the intermediate colours are less distinctly isolated, partaking of a mixture of the extreme tints.

The actual shadow, or dark space within the innermost fringe, is also larger than the geometrical shadow which would have been cast if the rays had passed exactly by the edge of the body in straight lines and been received on the same screen, and the illumination instead of being cut off sharply, fades continuously into the darkness of the shadow, extending indeed to a small amount even within the geometrical shadow. The space by which the actual shadow surpasses the geometrical in breadth, is independent of the form or the matter of the interposed body, and likewise, except in the case of a very slender body, of its linear dimensions. The dilatation of the shadow will therefore be most striking in the case of narrow bodies such as pins, hairs, &c.

When the interposed body is very narrow but of sensible width, streaks alternately brighter and darker will be found *within the shadow*, and a white line along the middle, when the body is of a long and slender rectangular form.

All these phenomena are seen more easily and with greater brilliancy if the light, instead of being received on a screen, be admitted directly into the eye armed with a lens or eye-piece.

If the incident light were homogeneous, such as pure red, blue, &c., as found in the spectrum, the colour of the fringes would of course be the same as that of the incident light, and the fringes would consist of simple alternations of light and shade. It is found that the scale of the fringes varies with the colour, the fringes being broadest for the least refrangible colours. Hence when the incident light is white the fringes are variously coloured, in consequence of the encroachment of the bright and dark fringes belonging to the various simple coloured lights of which, as we know, white light is compounded.

Sir I. Newton in his optics relates several modes in which he varied the experiments on the inflexion of light; and, in his queries, he suggests an explanation that light may be subject to the action of forces sensible only at very small distances from the surfaces of bodies; that under their influence the rays in their course near the edge of the body, instead of passing straightforward, describe very sinuous paths, with many contrary flexures, and thus they are found some turned inwards towards the shadow, others outwards, forming coloured bands; the curve surface, which is the locus of the intersections of all those diffracted rays, forming the envelope of the visible shadow. Little advance has been made beyond Newton's conjectures towards explaining, according to this doctrine, the curious phenomena of diffraction; and the explanation, incomplete as it is, has been shown by Fresnel to be subject to serious difficulties.

Very different has been the result with the theory which makes light to consist of undulations. This theory was first applied to the explanation of the phenomena by Dr. Young, who employed the principle of *interference*, the discovery of which we owe to him, and which he so successfully applied to the explanation of the colours of thin plates. The bending of light around an opaque body was assimilated to the bending of waves around an obstacle, and the internal fringes in the shadow of a narrow body to the *interference* of the light so bent round the opposite edges. That these fringes are incontestably produced by interference, he proved by cutting off the light passing either edge by means of an opaque screen placed either before or behind the narrow body, when the internal fringes immediately disappeared. The external fringes were attributed to the interference of the direct light with the light reflected from the edge of the diffracting body ('Phil. Trans.' for 1802, p. 12). Several of the observed laws of the phenomena were shown to be explicable on this hypothesis.

This explanation was in the first instance adopted by Fresnel; but in pursuing his researches he met with phenomena which opened his eyes to the insufficiency of the explanation, and at last led him to perceive that the various observed appearances flowed naturally from two grand principles—the principle of interference, and the principle of Huygens—which themselves are but particular applications of the general dynamical principle of the co-existence of small motions. In his celebrated memoir on diffraction ('Mém. de l'Académie,' 1821, tom. v. p. 339), he has followed out this theory into its mathematical details, and compared the results with observations both qualitatively and quantitatively, by a series of most careful measures; and the agreement is complete. The theory furnishes not a single disposable constant whereby a seeming accordance between theory and experiment might have been brought about, for the length of a wave of light, the only unknown constant involved, admits of being determined independently of diffraction by the interference of two streams of *regularly* reflected or refracted light.

About the same time, and independently, Fraunhofer was engaged in a series of researches on diffraction of a somewhat different class, namely, those produced when a luminous point or slit is viewed in focus through a telescope, and the object-glass is covered by a screen pierced with one or more apertures. The reader may easily observe phenomena of this kind by viewing a bright point, such as the image of the sun in the bulb of a thermometer, and covering the eye with a piece of fine gauze, or of tin foil or black paper pierced with one, two or three minute needle-holes, or apertures of other shape. The most remarkable instance observed by Fraunhofer was that of a fine grating through which was viewed a slit of light parallel to the lines of the grating. In this case spectra were formed so pure as to exhibit the fixed lines; and in this way Fraunhofer has measured with the most extraordinary accuracy the wave lengths corresponding to the fixed lines which he denotes by C, D, E, F, G, H. (Gilbert's 'Annalen,' Bd 74, s. 337.) This class of phenomena has been most elaborately investigated by M. Schwerd (Beugungserscheinungen, &c.).

DIFFUSION. This term has a somewhat extended application in modern science: thus we speak of the *diffusion of light*, and *of heat*, the *diffusion of gases* and *of liquids*: we also speak of a *diffusive power*. The diffusion of light is intimately related to its reflection. If we accept the optical definition of reflection, according to the law of equal angles, it would be impossible to account for the visibility of objects: the geometrical reflection would perfectly represent to the eye the source of the incident beam, but it would convey no idea of the size or colour of the reflecting surface. According to this law the image of the sun would be reflected from the surface of bodies just as if they were perfect mirrors, but the bodies themselves would not be seen: the moon would appear like a mirror reflecting the image of the sun: the candles in a room would be reflected by the walls and other objects, and nothing would be seen but the multiplied reflections of the flame. But as the surfaces of bodies are not perfectly reflective, but on the contrary, contain innumerable roughnesses which absorb a portion of the light and scatter the remainder, each roughness becomes the focus of a pencil of reflected light, the rays of which diverge equally in all directions, bearing with them the colour of the reflecting body. Thus each point of the surface forms an independent focus, by means of which each such point is made visible. This is called, somewhat improperly, *irregular reflection*, but there is nothing irregular in the phenomenon, for by means of it, light is diffused, and the illuminated objects become as it were secondary luminaries, and render objects visible which are not within the direct influence of the source of light, and these objects in their turn, by reflecting light irregularly illuminate others, and in this way the light is reverberated backwards and forwards so as to render objects visible which are far removed from any direct source of light. By means of this same property the atmosphere diffuses the light of the sun in all directions, and produces the phenomena of twilight. Similar phenomena are also to be noted with respect to heat, although it is not easy to determine the effects with as much precision. Radiant heat obeys the law of equal angles, but a portion of it that is not absorbed must be diffused by irregular reflection. This subject will come again under our notice in the article HEAT, and we content ourselves here with this slight indication of it.

The term *diffusion* as applied to gases and liquids, refers to that process by which such bodies when in contact, pass through each other and intermingle, although not necessarily related by chemical affinity. It was noticed by Priestley, that if a closed bladder containing oxygen gas be placed in a jar of hydrogen gas, the jar and the bladder will after some time each contain explosive mixtures of oxygen and hydrogen. This phenomenon, however, is now referred to *endosmosis*, or the *osmotic force*. [OSMOSE.] As an example of gaseous diffusion, we may instance the case of chlorine and hydrogen, the one being thirty-six times as heavy as the other, yet if a bottle of hydrogen be inverted, and connected by means of a long tube with a bottle of chlorine, the heavier gas will in a few hours creep up the tube to mingle with the hydrogen, and the light hydrogen will descend the tube to mingle with the chlorine, and this mixture will be equal in every part of the apparatus. Indeed, if sufficient time be allowed, this equal intermixture will take place between all gases and vapours which do not act chemically on each other. The rapidity with which this diffusion occurs varies with the density of the gases, and the more widely they differ in this respect, the more rapid is the diffusion. The rapidity with which a light gas diffuses into a heavy one may be shown by means of a *diffusion tube*, consisting of a glass tube 12 inches long, one end of which is closed with a dry porous substance, such as a plug of plaster of Paris: when this is filled with hydrogen gas at the pneumatic trough, and supported so that the water shall stand at the same level on the inside and on the outside, water will be seen to rise up the tube, and will continue to do so in opposition to gravity, until in a few minutes, it will be some inches higher than the water outside, in consequence of the gas escaping through the pores of the plaster, and diffusing itself into the air more rapidly than the air passes in and diffuses itself through the hydrogen. Experiments made in this way show that the diffusiveness of a gas is in the inverse proportion of the square root of its density. The density of air being 1, the square root of that density = 1, and its diffusiveness = 1, the density of hydrogen = 0·0692, the square root of that density = 0·2632, and its diffusiveness $\frac{1}{0\cdot2632}$ = 3·7994, or in an actual experiment 3·83. That is to say, while one measure of air is passing into the diffusion tube, 3·83 measures of hydrogen gas are passing out of it.

When different gases are introduced into the diffusion tube, each maintains its own rate of diffusion. The rate of diffusion is increased by a rise of temperature, but not so rapidly as the direct expansion by heat.

The process of diffusion performs an important part in nature. "Accumulations of gases, which are unfit for the support of animal and vegetable life, are by its means silently and speedily dispersed, and this process thereby contributes largely to maintain that uniformity in the composition of the aerial ocean which is so essential to the comfort and health of the animal creation. Respiration itself, but for the process of diffusion, would fail of its appointed end, in rapidly renewing to the lungs a fresh supply of air in place of that which has been rendered unfit for the support of life by the chemical changes which it has undergone." (Miller, 'Elements of Chemistry,' part i.)

The escape of a gas through a minute aperture into a vacuum is called EFFUSION, which see: and the passage of gases through capillary tubes into a rarified atmosphere belongs to TRANSPIRATION, while the passage of gases through diaphragms must be referred to *endosmosis*. [OSMOSE.]

Liquids diffuse themselves among each other, except in those few cases where they are not miscible, as in the case of oil and water, or but little miscible, as ether and water. In most cases however, the adhesion between the particles of dissimilar fluids is very perfect, so that they become completely incorporated; so much so, that an actual penetration of one body by the other seems to take place, since the mixture occupies less bulk than the liquids did separately. Thus 100 parts of alcohol mixed with 100 of water will measure only 196 parts, and the same proportions of sulphuric acid and water will measure only 185 parts.

The phenomena of liquid resemble those of gaseous diffusion. We have seen that hydrogen will descend to mix with chlorine, and that this heavy gas will ascend to diffuse itself among the particles of the hydrogen; so also, if a tall glass jar contain at the bottom one part of sulphuric acid, and over this two parts of the blue infusion of litmus, introduced so as not to mix with the acid, the heavier acid will in two or three days have diffused itself through the liquid, and the progress of the diffusion may be noted by the gradual change in colour from blue to red.

The subject of diffusion is greatly indebted to Professor Graham, who has obtained some interesting results by very simple means. His apparatus consisted of a number of 4-oz. jars with openings in the necks of 1·24 inch in diameter, for containing the trial solutions, and a number of 30-oz. cylindrical vessels for containing the small jars. The solution to be tried was poured into a 4-oz. jar to within half-an-inch of the top; it was then filled up with pure water, closed with a glass plate, and let down into the cylindrical vessel, into which was carefully poured about 20 oz. of distilled water; the glass plate was then cautiously removed, and the apparatus was kept undisturbed at a steady temperature for several days. When the result had to be examined, the mouth of the solution jar was again closed and the jar withdrawn from the vessel, the water of which was evaporated and the salt that had entered into it thus determined by weight.

From numerous experiments conducted in this way it was found: I. That when solutions of the same substance, but of different degrees of strength, were employed, the quantities diffused in equal times were *cæteris paribus* proportional to the quantity in the solution. Thus in 4 solutions of common salt, containing respectively 1, 2, 3, and 4 parts of salt per cent., it was found that in 8 days the quantities diffused were, in No. 1, 2·78 grains, in No. 2, 5·54 grains, or just double; in No. 3, 8·37 grains, or treble, and in No. 4, 11·11 grains, or four times the amount diffused from the first solution. II. That the quantities of the substances diffused from solutions containing equal weights of different bodies, varied with the nature of the substance, as in the following table. Each solution contained 20 parts of the solid in 100 parts of water, and was exposed for 8 days at a temperature of 60·5 degrees.

Substances used.	Sp. gr. of solution at 60°	Weight in grains diffused.
Chloride of sodium	1·1265	58·68
Sulphate of magnesia . . .	1·185	27·42
Nitrate of soda . . .	1·120	51·56
Oil of vitriol	1·108	69·32
Sugar candy	1·070	26·74
Barley sugar	1·066	26·21
Starch sugar	1·061	26.94
Treacle of cane sugar . .	1·069	32·55
Gum arabic	1·060	13·24
Albumen	1·053	3·08

Saline substances were found to arrange themselves in groups, the members of each group being equidiffusive, and the rates of diffusion in each group connected with the rate of diffusion of the other groups by a simple numerical relation. Isomorphous salts had generally equal rates of diffusion. Seven such groups were made out. In No. 1, were hydrochloric, hydriodic, and hydrobromic acids, and perhaps also nitric acid. These acids were found to be the most diffusible substances known. Group 2, contains hydrate of potash and probably ammonia. Group 3, nitrate of potash, nitrate of ammonia, chloride of potassium, muriate of ammonia, and chlorate of potash. No. 4, nitrate of soda, and chloride of sodium. No. 5, sulphate of potash, carbonate of potash, sulphate of ammonia, and ferro-cyanide of potassium; probably also chromate and bi-chromate, bi-carbonate, and acetate of potash, and ferrid cyanide of potassium. No. 6, sulphate and carbonate of soda; and No. 7, sulphate of magnesia. In the following table will be found some numerical results obtained by comparing together the squares of the times in which equal quantities of different salts are diffused. The second column shows the relative diffusibility of the different groups of the hydrochloric acid group; the third column gives the times required for the diffusion of equal weights of the members of each group; and the fourth shows the ratio of the squares of those times of equal diffusion.

Groups.	Rate of diffusion.	Times of equal diffusion.	Ratio of squares of times of equal diffusion.
1. Hydrochloric acid .	1·000	3·960	2
2. Hydrate of potash .	0·800	4·950	3
3. Nitrate of potash .	0·565	7·000	6
4. Nitrate of soda . .	0·462	8·573	9
5. Sulphate of potash .	0·400	9·900	12
6. Sulphate of soda . .	0·326	12·125	18
7. Sulphate of magnesia	0·200	19·800	48

III. Liquid diffusion is most regular in dilute solutions. It was also found that the quantity of a substance diffused from a solution of uniform strength increased with the temperature, but that the ratio of diffusion between different bodies at the same temperature was constant. It was found also, that of the whole quantity rather more than one-fourth was diffused during the first two days; the quantities diffused during each remaining period of two days being very nearly equal. IV. When two substances which do not combine chemically, but having different degrees of diffusibility, were mixed in solution and placed in a diffusion cell, the more diffusible substance passed out more rapidly than the other, so that a partial separation of the two bodies could be effected by this means. Thus the quantities of the carbonates of soda and of potash, diffused in the same time from a solution containing equal parts by weight, were as the numbers 35 and 65 nearly. It was even found, that in some cases chemical decomposition could be produced by liquid diffusion. Thus a solution of common alum (which is a compound of sulphate of alumina and sulphate of potash) arranged so as to diffuse into water, the sulphate of potash passed out more rapidly than the sulphate of alumina. V. It was found in the case of dilute solutions that one substance will diffuse into water which already contained another substance in solution, just as into pure water.

The reader who desires to pursue this subject further, is referred to Professor Graham's Papers, contained in the 'Philosophical Transactions' for 1850.

DIFLUAN. [Uric Acid.]

DIGAMMA, or **VAU**, is the name given by grammarians to a letter which once belonged to the ancient alphabet of the Greeks. It appears to have occupied the sixth place in that alphabet, for while *epsilon* is employed as the numerical symbol for *five*, the next letter, as that alphabet is now arranged, is the representative of *seven*. Moreover, this position of the digamma will correspond precisely with that of *vau* or *waf* of the Hebrew, and of *f* in the Latin alphabet, two letters of kindred power and form. A further argument may be found in the principles which would seem to have determined the arrangement of the Greek alphabet. [Alphabet, vol. i., col. 235.] The letter is still to be seen in many inscriptions. [Alphabet, vol. i., cols. 240-2, plate ii., Nos. 20, 21, 26.] With regard to the power of the letter, it is now the general and well-established opinion that it is equivalent to our own *w*. Its name has been evidently derived from the similarity of its symbol Ϝ to a repetition of the Greek *gamma* Γ.

The use of the digamma prevailed more particularly in the Æolic dialect of the Greek tongue. In the other dialects it was commonly dropped, particularly the Attic; and as this became the favourite dialect of Grecian literature, the digamma at last escaped from the alphabet; and even the Homeric poems, which had been written in a dialect still possessing the digamma, were presented to the Athenians without that letter, to the serious injury of the metre. But though the form of the digamma was not admitted into the Attic alphabet, the vowel *o* was occasionally used, so as virtually to represent it, as in *οιδα*, *οικος*, *οινος*, equivalent to ϜΙΔΑ, ϜΙΚΟΣ, ϜΙΝΟΣ (comp. the Latin *video*, *vicus*, *vinum*); and it was altogether superfluous to prefix the digamma, ϜΟΙΚΟΣ, as was sometimes done. Other substitutions for the digamma are *β*, as *βοινος* for *Ϝοινος* or *οινος*, *εβαω* for *εϜαω* or *εαω*, *βροδον* for *Ϝροδον* or *ροδον*, *βριζα* for *Ϝριζα* or *ριζα* (Cf. Germ. *wurz-el* and our *wort* = *root*); secondly, *ου*, as *Ουαρρων* for Varro; thirdly, *υ*, as *αυρηκτος* for *α-Ϝρηκτος* or *αρρηκτος*, *αυως* for *αϜως* or *ηως*. Whether *γ* is ever substituted is disputed. Some, supported by the analogy of the French habit, as *gâter* for *vastare*, and the repeated authority not only of the Hesychian glosses but of MSS., hold that *γεθεν*, *γειματα* or *γηματα*, *γεντο* are genuine dialectic varieties of *Ϝεθεν*, *Ϝειματα*, *Ϝεντο*. Ahrens on the other hand regards the Γ as a clerical error for Ϝ. A still more violent substitution is that of *ρ* for *Ϝ*, as *δεδροικως* for *δεδϜοικως* or *δεδοικως*, of which we have the converse in our *wubbish* for *rubbish*.

The Latin language, being more closely connected with the Æolic dialect of the Greek, is abundant in the use of this letter; for the true pronunciation of the *v* or *u consonans* must have been the same as our *w*, or it could not have so readily interchanged with the vowel *u*. The Greek words *ωον*, *εαρ*, *εσπερος*, *εστια*, *ιον*, appear in Latin as *ovum*, *vēr*, *vesperus*, *vesta*, *viola*. In the last instance indeed there are two other points of difference, the Latin word being feminine, like *rosa* compared with the Greek *ροδον*; and secondly, a diminutive, which is well suited to the size of the flower. Sometimes a *b* appears in the Latin word, where the Æolic Greek must have had the digamma, as *probus* compared with *πραῦς*; or an *f*, *Formiæ* compared with *Ormiæ*.

The disappearance of the digamma in one dialect and its retention in another is in perfect accordance with what is seen in modern languages. In our own we have ceased to pronounce the *w* in *who*, *whose*, *two*, *sword*, *answer*, *whole*; while in *one* and *once* we have the sound without the character, and yet drop it again in *only*. The Danish dialect of the Teutonic language is remarkable for throwing off the *w*, thus *word* in the mouth of a Dane is *ord*.

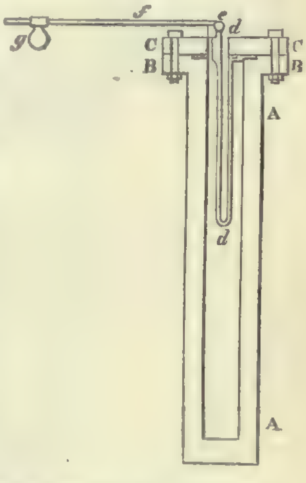
For the assertions of the grammarians and the opinions of the learned with regard to the digamma, see Kidd's edition of Dawes's 'Miscellanea Critica,' pp. 175-335. The editor has given a list of the Greek words which he supposes once to have possessed this letter. A more complete discussion of the subject is to be found in Ahrens, 'De Græcæ Linguæ Dialectis.'

DIGEST. [Corpus Juris; Justinian's Legislation.]

DIGESTER. A strong steam-tight vessel, usually of iron or copper in which water and other materials can be heated considerably beyond their boiling points; this form of apparatus was first contrived by Papin, and is hence frequently termed Papin's digester. The following is a description of two vessels of this description which are frequently employed by chemists.

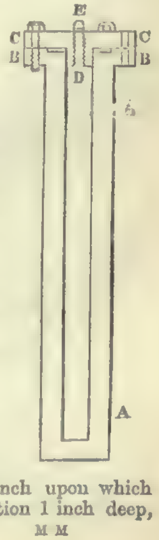
The first is constructed entirely of Low Moor wrought-iron, and consists of a cylinder A A (*fig.* 1), closed at the bottom, and welded in one piece by the steam-hammer. The cylinder is 18½ inches long, ⅝ inch in thickness, and 3 inches internal diameter; it is furnished at top with a flanch, B B, 1⅜ inch broad and ⅝ inch thick, its upper surface turned true, and having an internal annulus sunk $\frac{1}{20}$ inch below the level of the surrounding surface. The cap of the digester, C C, is made to fit upon this flanch, with which it corresponds in thickness and diameter; it is furnished with a projecting face ¼ inch deep, fitting the mouth of the cylinder exactly. Within the circle of this projecting face, the cap is perforated by two apertures, into one of which is securely fixed the cast-iron tube *d d*, closed at the bottom, 6 inches long and ¼ inch internal diameter, forming a mercury bath for the reception of a thermometer. The other aperture, which is bouched with brass, serves as the bed of the safety valve *e*, which consists of a piece of brass wire ¼ inch diameter, slightly flattened on two sides and furnished with a head accurately ground to the surface of the cap: pressure is applied to this valve in the usual manner by the lever and weight *f g*. Both the flanch and cap are perforated by four holes for the reception of four screw bolts ⅝ inch in diameter, which are inserted from below, and work into nuts that can be tightly screwed up by a lever key. The whole of the pressure produced by these screw bolts is made to take effect exclusively upon the surface of a leaden washer ¼ inch thick, placed in the sunken annulus above mentioned: and thus the apparatus is made perfectly impervious to gases and vapours, even under the enormous pressure of more than 100 atmospheres. In this digester, volatile liquids enclosed in glass tubes of large dimensions and moderate thickness of glass, may be exposed to any temperature below redness with safety. Water is generally used in this digester, but other and less volatile liquids may of course be substituted if desired: in most experiments, however, it is important that the pressure upon the exterior of the glass tubes should not be much less than that in their interior, and this condition is generally secured by the employment of water in the apparatus.

Fig. 1.



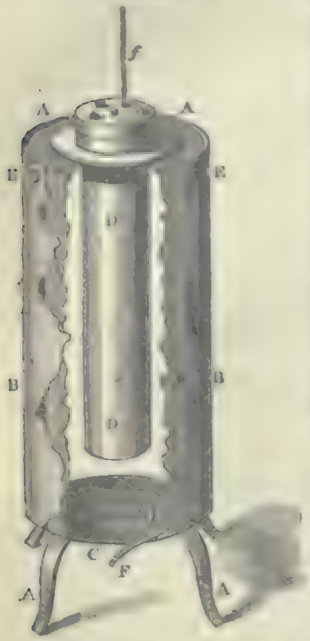
The second digester is made of wrought copper and is of smaller dimensions, being especially designed for the heating of chemical substances without the intervention of glass tubes. It consists of a wrought copper tube, A A (*fig.* 2), 18 inches long, 1½ inch internal diameter, and ⅛ inch in thickness, drawn from a solid mass of the metal by a recently invented process. This tube is closed at bottom by a screw plug, and is furnished at top with a brass flanch, B B, 1⅜ inch broad and 1 inch thick, screwed upon the copper tube: the vessel thus formed is closed by the brass cap C C, of the same dimensions as the flanch upon which it fits. The cap is furnished with a central projection 1 inch deep,

Fig. 2.



fitting the copper tube, and pierced with a central aperture D, tapped to receive the screw plug E, which, with the intervention of a collar of lead, effectually closes the aperture. The cap C C is secured to the digester by three screw bolts ¼ inch in diameter, which are inserted from above and screw into the lower flanch. Perfect impermeability to gases is secured, as in the iron digester, by a sunken annulus and a ring of lead. When it is desirable to collect the gases evolved during any operation in this digester, the plug E is replaced by a carefully made stopcock, to the nozzle of which a gas-delivery tube can be attached, when the reaction is completed. This digester is heated by means of a cylindrical copper oil-bath placed in a gas-stove, as shown in *fig.* 3. The gas-stove consists of a strong wrought-iron framework, A A, around which is fixed the sheet-iron cylinder B B closed at the bottom, but furnished with a draught regulator C, and contracted at top by a ring of sheet iron so as just to admit the cylindrical oil-bath D D, the flanch of which rests upon the upper extremities of the wrought-iron framework, which are turned inwards for this purpose. The sheet-iron cylinder is surrounded by another of polished tin plate to prevent the too rapid radiation of heat; there is an interval of half an inch between the two cases, and both are pierced with holes at E for the exit of the products of combustion. A ½-inch copper pipe, F, pierced with eighteen or twenty small apertures, forms the gas-burner. By this arrangement, it is easy to maintain an almost constant degree of heat for any length of time. The temperature is ascertained by the thermometer *f*, immersed in the oil-bath through an aperture bored in the cap and flanch of the digester for this purpose. This gas-stove is also used for heating the iron digester, but without the intervention of the oil-bath.

Fig. 3.



DIGESTION, in Chemistry, and especially in Pharmaceutic Chemistry, is the exposure of any substance to partial or total solution in a fluid, either at common temperatures or with a gentle heat: thus in the preparation of tinctures, the substance whose active principle is to be extracted is said to be *digested* in alcohol or spirit of wine, generally diluted with water. It is commonly performed in a glass flask or bolthead which should not be more than half filled, and covered with a piece of wet bladder, so that the evaporation of the menstruum or spirit may be prevented as much as possible; if the heat be so great as to endanger the bursting of the vessel or the bladder, the latter should be pierced with one or more small holes.

The flask may be heated either by means of the sun's rays, of a common fire, or of the sand-bath, or a stove: when the heat is so great that it would occasion the loss of a valuable menstruum, as spirit of wine, without any provision for condensing it being employed, a distilling apparatus should be made use of. Formerly a method of digestion called *circulation* was resorted to; this consisted in luting a close head on the digesting vessel, in which the vapour was condensed, and ran back into the digester without loss, it being condensed in the head merely by exposure to the air.

DIGIT, a finger, a term employed to signify any symbol of number from 0 to 9. According to the original application of the term, the first ten numbers should be called digits, but universal practice employs the word to signify the ten symbols used in reckoning number. Thus ten (10) is a number of two digits.

DIGITALIC ACID. A white crystalline acid possessing a peculiar odour, and found in purple foxglove. It is very soluble in water, less so in alcohol, and still less soluble in ether. It readily undergoes spontaneous decomposition, and has not been analysed.

DIGITALIN ($C_{20}H_{16}O_8$). This name has been given to the active principle of the purple foxglove; little is known of its properties, and it has by some been supposed to be a mixture of three bodies, called *digitaline*, *digitalin*, and *digitalose*. Further, *digitalicrine*, and *digitalosine* are also the names of bodies derived from the same source. The whole subject requires re-investigation.

DIGITA'LIS PURPU'REA, fox-glove, a biennial plant, of which the leaves and seeds are used. The leaves are sometimes accidentally confounded with those of different species of Verbascum, and of the Conyza squarrosa. The most powerful leaves are those procured from plants growing on the sunny sides of hills, those of the second year only should be collected. They must be carefully dried, and protected from damp, and kept in the dark. The active principle appears to reside in an extractive substance, which by careful evaporation may be crystallised, and to which the name of Digitaline has been given. This principle is soluble in water, in alcohol, and sparingly in ether. It is very poisonous. One grain dissolved in a little water killed a rabbit in a very short time. Digitalis is given in powder, made into pills, or in an alcoholic tincture. Diversity of opinion exists respecting its primary action on the system, some writers considering it as primarily a stimulant, and the sedative effect a consequence of the previous excitement; others regarding it as a direct sedative. It is most likely that it acts in both ways according to the dose, and frequency of administration. If a small dose be given, and repeated at short intervals, a stimulant action will be most obvious, followed at a considerable interval by a sedative effect. If on the other hand a large dose be given at first, the sedative action is immediately displayed. The effect varies also with the position of the person, being different according as he is standing, sitting, or reclining.

Digitalis is the most perfect example known of a cumulative poison, as it may be used for some time, if the doses be small, without producing any manifest effect for several days, when suddenly faintness, intermittent pulse, giddiness, and other alarming symptoms appear. These are best combated by vital stimulants, such as warm brandy and water.

Digitalis has the power of reducing in a remarkable degree the heart's action, bringing down the pulse from 120 or more to 50 or 40 beats in a minute, and causing it to become at the same time intermittent. On this power depends its medical value in some diseases. It is remarkable, however, that while it thus lowers arterial action, it excites the absorbents and the kidneys to increased action, and so proves a valuable diuretic in dropsy and some other diseases. It is most useful in organic affections of the heart, and in the latter stages of some inflammatory affections, such as pneumonia, in phthisis pulmonalis, chronic peritonitis, and irritative or nervous fever. In the inflammatory or turgescent stage of hydrocephalus acutus, along with calomel, Golis states it to be very valuable.

As a diuretic, it is, like most medicines of that class, uncertain in its effects: it seldom answers if much inflammatory action exist when it is exhibited. To render it more certain it is generally given along with calomel, and squills, or some other diuretic. Digitaline has been recommended by Dr. Christison and others.

DIGITOLEIC ACID. A crystalline fatty acid, found in the purple foxglove. A number of salts have been prepared from it, but neither these nor the acid itself have been analysed.

DIGNITIES. [TITLES OF HONOUR.]

DI-IODOCODEINE. [OPIUM, ALKALOIDS OF].

DILAPIDATIONS. In its legal sense, this term is confined to the pulling down or destroying, in any manner, any of the houses or buildings belonging to an ecclesiastical benefice, or suffering them to run into ruin or decay, or wasting or destroying the woods of the Church, or suffering any wilful waste in or upon the inheritance of the Church. An incumbent is bound to keep the buildings in repair, restoring and rebuilding where necessary according to the original form, without addition or modern improvement, but he is not bound to supply or maintain anything in the nature of ornament, such as painting (unless necessary to preserve exposed timbers from decay), whitewashing, and papering. For damages calculated on this principle the successor may bring his action, either in the courts of common law or in the spiritual court, against his predecessor, or, if he be dead, against his executors.

The right to damages for dilapidations, as between other persons, is governed either by the laws relating to waste and repairs, or by special contract.

DILATATION. [HEAT.]

DILATATION OF THE HEART. [HEART, DISEASES OF.]

DILIGENCE, in the law of Scotland, is an expression nearly equivalent to "process" in the law of England. It includes the various means by which the person may be seized and imprisoned, the property attached and disposed of, to the end of enforcing payment of debt or performance of any civil obligation; and witnesses compelled to give their evidence, or to produce books, writings, &c. It would not give a comprehensive view of the object of this procedure to say that it is for the purpose of carrying out the judgments of the courts of law, because it is a characteristic of Scottish procedure that not only will an agreement properly executed between parties to allow diligence to proceed without a judgment (as in a warrant to allow judgment to be entered up in England) be a sufficient warrant for diligence, but there are certain pecuniary obligations, of which it is the characteristic that summary or the more rapid kind of diligence can proceed on them if they are not in any way vitiated or imperfect. These documents are bills of exchange and promissory notes, and the facility of recovering the debts contained in such documents, by a rapid method of execution, is a marked feature in the mercantile code of Scotland, and one which is believed to have beneficial effects. Before diligence can issue, such a document must be protested and registered in the books of some competent court, and thence the diligence issues, as if it were founded on the decision of the court. The registers being accessible to the public on payment of certain fees, this facility for tracing the initial steps of bankruptcy is made use of by members of the mercantile community of Scotland, who have a machinery by which they can inform each other of the persons whose names appear on the register.

Diligence is either against the person, by imprisonment, or against the estate, by attachment and sale. The latter class is divided into two kinds—that against the heritable or real estate [ADJUDICATION], and that against the moveable. This latter admits of a subdivision into an attachment of property in the debtor's possession, called in the ordinary case Poinding [POINDING], but where it is by a landlord for rent, sequestration; and an attachment, in the hands of a person who is owing money to the debtor or holds property belonging to the debtor in his custody. [ARRESTMENT.] Formerly diligence, in the greater number of cases, proceeded on the clumsy fiction that the debtor, being charged to pay in the name of the sovereign and refusing, was to be denounced a rebel by a messenger at arms, who certified that he performed the denunciation by three blasts of a trumpet, and it was nominally as a rebel that his person or estate was seized. A more simple and economical procedure has now been substituted.

DILITURIC ACID. An acid, the existence of which has not been fully proved, said to be produced by the action of boiling hydrochloric acid upon alloxantine.

DILUENTS comprise those liquids which are used to dilute the fluids of the human body, and thereby modify their nature. They are employed when the secretions are too viscid, or the contents of the stomach, of the intestines, or any of the glands are too acrid, and also when the heat of the body, as indicated by thirst, &c., is too great, and causes a feeling of uneasiness. They manifest their beneficial effects most quickly when the contents of the stomach or upper part of the intestines require to be diluted, as in the case of many poisons; but they also reach the kidneys or skin in a very short time after their introduction into the system, and render less acrimonious the secretions of these organs. Their utility in allaying the thirst of patients affected with fevers and other inflammatory complaints is well known, and from such patients they ought never to be withheld, as they were at one time, when erroneous notions on the subject prevailed, as they not only mitigate the sufferings of the invalid, but often determine to the skin, and cause a critical perspiration. It is equally cruel and injurious to withhold drinks of a mild kind from dropsical subjects, though they require to be used by such persons in greater moderation.

Water is the simplest, and often the best diluent, but it may be rendered more agreeable in some cases by being made into toast-water, or by having acid or other substances added to it. Whey or buttermilk are also agreeable diluents in many cases. The excessive use of fluids at meal-times seems to be hurtful to digestion; and diluents appear to be less proper for persons of a soft and lymphatic constitution than for the robust and sanguine. Children of a scrofulous constitution do not prosper so well on a fluid as on a dry diet; they should therefore be allowed liquids in a very moderate degree, especially towards evening. A dry diet is rigidly enforced on all persons training for athletic feats.

DIMENSION (algebra), a term which is used in the same sense as DEGREE. Thus x^2y is of three dimensions or of the third degree. In geometry, length is of one dimension, surface of two, and solidity of three. Thus geometry of three dimensions means solid geometry.

DIMETHYLALLOXANTIN. [AMALIC ACID; CAFFEINE.]

DI-METHYLAMINE. [ORGANIC BASES.]

DIMETHYLMUREXID. [CAFFEINE.]

DIMETHYLOXAMIDE. [OXAMIDE.]

DIMETHYLPARABANIC ACID. [CAFFEINE.]

DIMETHYL-UREA. [UREA.]

DIMORPHISM. [ISOMORPHISM.]

DINAPHTYL-CARBAMIDE ($C_{42}H_{16}N_2O_2$). A derivative of carbamide, prepared by the action of heat upon oxalate of naphtylamine.

DINAPHTYL-SULPHOCARBAMIDE ($C_{42}H_{16}N_2S_2$). An unimportant derivative of carbamide. It is dinaphtyl-carbamide in which the oxygen is replaced by sulphur. [DINAPHTYL-CARBAMIDE.]

DINITRANILINE ($C_{12}H_5(NO_4)_2N$). [ANILINE.]

DINITROBENZOIC ACID. [BINITROBENZOIC ACID.]

DINITROBENZOLE. [BENZOLE.]

DINITROETHYLIC ACID ($N_2C_4H_5O_3$). An acid obtained in combination with oxide of zinc by the action of zincethyl upon binoxide of nitrogen. This acid may be regarded as a double equivalent of binoxide of nitrogen (N_2O_4), in which one atom of oxygen is replaced by one of ethyl, the reaction being quite analogous to that by which Wanklyn succeeded in producing propionic acid from sodium-ethyl and carbonic acid. Dinitroethylic acid is therefore an analogue of propionic acid. The acid itself is very unstable, and many of its salts deflagrate violently on exposure to heat.

DINITROPHENYL-CITRACYNAMIC ACID ($C_{10}H_6(C_{12}H_3(NO_4)_2)NO_8$). A derivative of citric acid.

DI'OCESE (διοίκησις, *dioikésis*, literally "administration"), in the time of Constantine and afterwards was used to designate one of the civil divisions of the empire; but it is now used only in reference to ecclesiastical affairs. A diocese is a district over which the authority of a bishop extends. It is equivalent to BISHOPRIC.

DIOCLES. [CISSOID.]

DIO'NE, an ocean nymph, or female Titan, was, according to Homer and Hesiod, the daughter of Oceanus and Tethys; but some later writers make her the daughter of Uranus and Ge. She was the mother of Aphrodite by Zeus; and Homer describes her as receiving Aphrodite in Olympus, after that goddess had been wounded before Troy, and soothing her with the assurance that Diomedes should die early and childless. ('Iliad,' b. v., 370-406.) Dione was worshipped in the temples of Zeus, and had a grove dedicated to her at Lepreon, in the Peloponnesus. She is often represented by Greek sculptors: usually with a certain resemblance to Aphrodite, but of a fuller and more matronly form. The beautiful statue in the second Græco-Roman saloon at the British Museum, commonly called the Townley Venus, is by several authorities considered to represent Dione, and it now bears the inscription Aphrodite or Dione.

[Dione, or Aphrodite: from a marble statue in the British Museum.]

DIONY'SIA (Διονύσια), festivals held in honour of the god Dionysus. The most important of such festivals, and those which alone deserve to be specially mentioned, were held at Athens and in Attica; and these are important by reason of their being the occasions on which all the dramatic exhibitions of the Athenians took place. Both the tragedy and comedy of the Athenians arose ultimately from parts of ceremonies, which prevailed in very early times among the Greeks, at the festivals of Dionysus (Aristot. 'Poet.' 4. 14); and it is alike a consequence and a proof of this origin, that the dramatic exhibitions and contests among the Athenians, from the earliest to the latest times at which we can trace them, always took place at some one of the Attic Dionysia.

These Attic Dionysia were four in number. Enumerated in the order of time, according to the Attic year, they were: 1, the Lesser or Rural Dionysia, held in the month Poseideon; 2, the Lenæa, held in the month Gamelion; 3, the Anthesteria, held in the month Anthesterion; and 4, the Great or City Dionysia, held in the month Elaphebolion. They were held in four consecutive months, the first of which, Poseideon, coincides with part of December and part of January, and the last, Elaphebolion, with part of March and part of April.

We proceed to speak of these festivals separately, and in the order in which they occurred in the Attic year.

1. *The Rural or Lesser Dionysia*, was a festival celebrated all over Attica, the other three being confined to Athens. This appears to have been the oldest of the Dionysia. It was a festival of the vintage, and though it may appear to have been held somewhat late in the year (in the latter part of December), it was not held later than the vintage now takes place, in a more rigorous climate, in some of the vineyards producing the Tokay wine. The Rural Dionysia were celebrated by means of separate festivals in all the demes of Attica; the expenses of these separate festivals fell on the several demes and the performances, processions

and banquets, of which the festivals consisted, were under the superintendence of the several demarchs. It is inferred from the law of Evagoras, cited by Demosthenes (Mid. p. 517), and an inscription contained in Boeckh's Public Economy of Athens (App. viii.), that Athens joined, on the occasion of the Rural Dionysia, in the festival celebrated at Piræus. At the dramatic performances of these rural festivals, plays that had before been represented either at the Lenæa or the Great Dionysia, used to be repeated. Of the procession, in which was carried the phallus, and in which was sung the phallic hymn, there is a sketch in miniature in the 'Acharnians' of Aristophanes (v. 230, fol.). At all these festivals great licence of speech and conduct was allowed; but at this the licence was the most unbounded.

2. *The Lenæa*, so called from a wine-press (ληνὸς), whose erection, in an inclosure called for the same reason *Lenæum*, lying originally a little out of the city and near a marsh (Λίμναι), it was supposed to commemorate, may, like the Rural Dionysia, be considered a vintage-festival. Boeckh thinks that a festival that went by the name of *Ambrosia* was the same with the Lenæa. The Lenæa were celebrated also among the Ionian states in Asia Minor, they having carried over with them at their migration the custom of the mother-country; and the Attic month Gamelion, in which the Lenæa were held, received in the Ionian calendar the name Lenæon. In Athens, the Lenæa were under the superintendence of the king-archon, and were celebrated with a public banquet at the expense of the state, a procession, and with dramatic exhibitions. As regards these last, we find that they consisted chiefly of new comedies. There are, however, instances of tragedies represented at the Lenæa, as also of comedies at the Great Dionysia, in the performances at which festival tragedies greatly predominated. It will help to show the relation between the Lenæa and the Great Dionysia that at the former foreigners were not, as at the latter, excluded from choruses, and also that the resident aliens (μέτοικοι) might at the Lenæa serve as *choragi*, which again was not permitted at the Great Dionysia.

3. *The Anthesteria*, deriving its name from the time of year at which it was held, the month of flowers, is a festival differing materially from the other three, inasmuch as it appears to have comprehended no public dramatic performances. It is inferred however by Hermann, from a law mentioned in the Lives of the Ten Orators (Pseud. Plut. vi. p. 253), and from other stray allusions to contests taking place at this festival, that plays were now rehearsed before small audiences, which were to be performed at the Great Dionysia in the succeeding month. Neither was there at the Anthesteria, as at the Lenæa and Great Dionysia, a public banquet provided by the state; but a certain sum, it is supposed, was given to each citizen, with which he was to provide his own repast. (Plut. 'Resp. Ger. Pr.' c. 25.) The festival lasted during three days, which respectively bore the names *Pithoegia*, *Choes*, and *Chytri*. On the first day, as is to be inferred from the name, the wine of the preceding vintage was broached and tasted, and on the second, we may suppose, the new wine was drunk. It was on this day that persons were initiated in the mysteries of Dionysus. On the second day there were various games; on the third, flowers, &c. were offered to the god. This was accounted a festival of great sanctity, and included many mysterious ceremonies for which none but the wife of the king-archon and a small number of priestesses (γέραιραι) were qualified. One ceremony was a mock marriage between the king-archon's wife and Dionysus. (Demosth. 'Neær.' p. 1369.) The Anthesteria were, like the Lenæa, under the superintendence of the king-archon. As during the Roman Saturnalia, the slaves enjoyed a temporary freedom during this festival; it was a custom also to send presents, and, as at the Roman Quinquatria, to pay one's instructors on the occasion of the Anthesteria. (Athen. x. 437.)

4. *The City or Great Dionysia*, or *Dionysia* without any epithet, the most splendid of the four festivals, were under the superintendence of the chief archon (ἄρχων ἐπώνυμος). This festival was held at a time when Athens was filled with foreigners, those bringing the tribute from her dependent states, and others. (Aristoph. 'Ach.' 474, &c.) It was celebrated with a public banquet at the expense of the state, with a magnificent procession, and with dramatic performances, which consisted chiefly, as has been said in describing the Lenæa, of tragedies. Plays which had once won a prize were not allowed to be repeated, though a special exemption from this rule was granted to the plays of Æschylus upon his death, and subsequently to those of Sophocles and Euripides.

The times and occasions of the institution of these several festivals are wrapped in obscurity. The Rural Dionysia, Lenæa, and Anthesteria, were connected with a rural worship of Dionysus [DIONYSUS], and were, it may be safely said, antecedent to the Great or City Dionysia; and it is, in comparison with this festival that Thucydides (ii. 15) calls the Anthesteria, more ancient. The Lenæa and Anthesteria were festivals held in the deme Lenæus before it was inclosed within the city. The institution of the great Dionysia seems to be referred to in a legend, which relates that Pegasus brought an image of Dionysus Eleuthereus from Eleutheræ to Athens. Boeckh connects this with an historical tradition of the migration of the Eleutherians from their town to Athens, and conjectures that the migration, and, as he supposes, consequent institution of the Great Dionysia, preceded by a little the return of the Heraclides (1124 B.C.). Welcker, who assigns to the epithet Eleuthereus and other epithets of Dionysus a political meaning, connects with the progress of his rites in the Athenian state the progress of political liberty.

The grand features of these festivals were the dramatic performances, the secret rites, and the public processions. Of the dramatic performances we have spoken above. Of the secret rites little is really known. The processions were what perhaps most distinguished them in the popular eye from the other public festivals of Attica. The Dionysia were a season when riotous merriment and drunkenness were universal. The bounty of the wine god was symbolised in the unlimited enjoyment of his worshippers. In the procession Dionysus himself was represented, attended by Nymphs, Lenæ, Bacchantes, Fauns, Satyrs, &c. The men, drunk with wine, were disguised with skins and masks, their bodies were painted, they were crowned with garlands of ivy, and carried thyrsi in their hands; while the female bacchantes, &c., danced along in a state of ecstatic phrensy. These Dionysian processions afforded favourable opportunities for the display of the freer forms of Greek art, and some of the most beautiful relievi, sculptured and painted vases, &c., have Dionysian processions or characters for their subjects. Many of these may be seen in the British Museum. The beautiful figure of a bacchante engraved below is supposed to be the work of Scopus. The cut of a Dionysian procession is from a large marble vase.

[Bacchante, from the British Museum.]

The *bacchanalia*, as the Roman festive rites in honour of Bacchus were called, must be distinguished from the Greek Dionysia. The bacchanalia were celebrated every third year, and were hence called trieterica. At them a mixed crowd of men and women, intoxicated with wine, clothed in deer-skins and Asiatic robes, and carrying thyrsi in their hands, ran up and down the country shouting, beating drums and cymbals, and crying, "Evoe! Io Bacche! Evan!" &c. They are said to have been introduced into Rome from Etruria. (Liv. xxxix. 8.) Such fearful excesses, however, were early brought into practice at the secret initiatory rites, that in the year 186, B.C., the consuls laid a report of the proceeding before the senate, and afterwards before an assembly of the people, and were, in consequence of the disclosures, invested with extraordinary powers for their suppression. They accordingly issued a proclamation for the suppression of the bacchanalian orgies throughout Italy; and directed all persons known to have participated in the private meetings to be summarily arrested. As many as 7000 persons are said to have been initiated; and the trials of those seized lasted thirty days. Henceforth only a simpler and comparatively harmless festival, the *Liberalia*, was celebrated in Rome annually, on the 16th of March. It was on this day that Roman youths were invested with the toga virilis.

[Dyonisian Procession, from a Vase in the British Museum.]

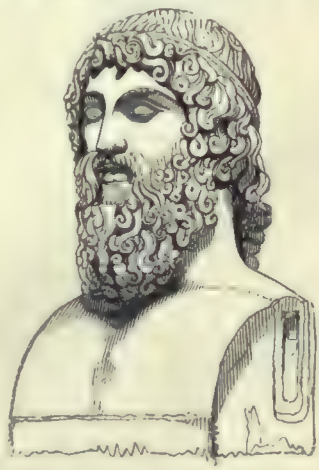
DIONY'SUS (*Διόνυσος*), and later Bacchos (*Βάκχος*) of the Greeks, Bacchus of the Romans, the god of wine, the representative among the male deities of the productive power of nature. In the common narrative he appears as the son of Zeus and Semele. Hera, being jealous of Semele, assumed the form of her old nurse Beroë, and thus persuaded Semele to request Zeus to visit her in his majesty as he was accustomed to visit Hera. Zeus having beforehand promised to grant her prayer, was obliged to comply, and the consequence was, as Hera foresaw, that Semele was destroyed by the lightning of the thunder-god. But before she perished she gave premature birth to Dionysus, who was taken by Zeus and enclosed in his thigh till he arrived at maturity. During his infancy Dionysus was nourished by the nymphs in Naxos, and Hermes and the Muses assisted in his education on Mount Nysa. When he grew towards manhood Hera threw him into a fit of madness, as she had before done to some of the nymphs who had followed him. In this state he wandered long and far over the earth, bestowing rewards on those who treated him kindly, and punishing those who refused to welcome him or accept his gifts. In the course of his wanderings he visited Rhea, who instructed him in the mysteries which afterwards formed so important a part in his worship. He was accompanied wherever he went with a crowd of attendants, consisting of Bacchantes, the Lenæ, the Naiades and Nymphs, the Thyades, the Mimallones, the Tityri, Pan, Silenus, the Fauns, and the Satyrs, whose riotous and frenzied proceedings' typified the influence of the fruit of the grape, the culture of which he disseminated throughout the earth. The various adventures of Dionysus whilst on the earth are told by the Greek and Roman writers at great length; but they are too well known, and would require too much space to recapitulate here. When he had completed his wanderings, he was received into Olympus, whither he carried also his mother, having brought her out of Hades, and changed her name to Thyone.

The worship of Dionysus seems to have arisen from that "striving after objectivity" (Wachsmuth, 'Hellen Alterthum,' ii. 2, p. 113) which is the characteristic of a primitive people, and which leads man in his rude state to the worship of the active and productive powers of nature. It does not fall within the nature of this work to discuss the inferences drawn from the old traditions by modern mythologers. These deductions, and especially the description of the mystical character of Bacchus, as distinguished from his worship as the god of wine, may be seen fully developed by Creuzer ('Symbolik,' theil. iii. pp. 83, 266; pp. 319–366), whose theory, however, of the Indian origin of the Bacchic rites, though ingenious, does not appear to be established by sufficient external evidence. The southern coast of Thrace seems to have been the original seat of this religion, and it was thence introduced into Greece shortly after the colonisation by the Æolians of the Asiatic coast of the Hellespont. The admission of the identity of Osiris and Dionysus by Plutarch and other mythological theorists, as well as Herodotus's simple statement of the assertions of the Egyptian priests to that effect, is no proof of the common origin of the worship of this divinity in Egypt and Greece; but there is no doubt that certain modifications of the Dionysian rites took place after the commencement of the intercourse of the Ionians with the Egyptians. These rites, the distinguishing feature of the worship of Dionysus, have been already described. [DIONYSIA.]

The worship of Bacchus is intimately connected with that of Demeter: under the name of Iacchus he was worshipped along with that goddess at Eleusis. [DEMETER; ELEUSINIA.] Virgil invokes them together ('Georgics,' i. 5) as the lights of the universe. According to the Egyptians they were the joint rulers of the world below. (Herod. ii. 123.) Pindar calls Dionysus "the companion of Demeter" (*χαλκοκρότου πάρεδρον Δαμάτερος*), and in a cameo he is represented sitting by the goddess in a chariot drawn by male and female centaurs. (See Buonarotti, 'Osservazioni sopra alcuni Medaglioni Antichi,' p. 441; Mariette, 'Traité des Pierres Gravées,' t. ii. p. i.)

Dionysus himself, his adventures, and his associates, were among the most favourite subjects of Greek and Græco-Roman art. Müller has very tersely and clearly indicated the range and character of the Dionysian life and cycle. "The whole of the wondrous life of Dionysus—at least, so far as it did not withdraw itself from representation by a decidedly mystical tendency—admits of being traced in works of art. First, the significant double-birth from Semele's dead body and the thigh of Zeus; then how Hermes carries the child, carefully wrapped up, to his nurses, the august form of the earth receives it, the nymphs and satyrs cherish it, and his divine and wondrous nature is unfolded amid joyous sports. Then how, surrounded by the noise and tumult of his thiasos, he finds the gracious bride Ariadne (a Cora of the Naxian worship), at the same time, however, without active participation, and, as it were, wrapped in a pleasing dream, and then rides to meet her, or with her, in a bridal chariot (wherein the leading of Ariadne up to Olympus may suggest itself to the mind). The Naxian solemnisation of the nuptials becomes itself a representation of the gayest and happiest life, in all abundance of the gifts of nature. But Dionysus also appears, in a work of the best period of art, in a gracefully tender relation to his mother, who is restored from the nether world. Lastly, we see him in the circle of frenzied Mænads, subduing and punishing Pentheus and Lycurgus, the insulters and foes of his worship, and also the piratical Tyrrhenians, by means of his bold satyrs, and in rich relievo representations (in which the victorious

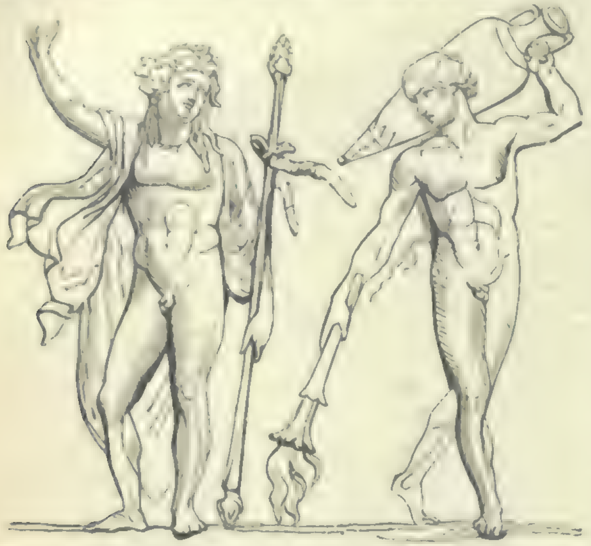
[The Bearded Dionysus and a Bacchante, from a bas-relief in the British Museum.]



[Bust of the Bearded Dionysus, from the British Museum.]

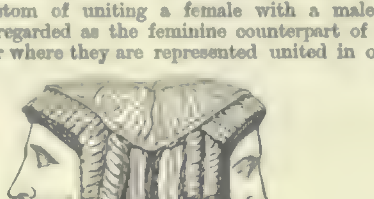
expeditions of later Macedonia were mythically typified) celebrating the triumphs of the conquest of India." ('Ancient Art,' p. 492.)

On the form and dress of Dionysus almost all the ancient testimonies have been collected by F. G. Schön in an ingenious dissertation on the costume of the characters in the Bacchæ of Euripides; and by Müller as above. The earliest forms of the god represented him as a man of mature age, with luxuriant curling hair, bound by the mitra, with a flowing beard, and open expression of face, and enveloped in ample drapery: when this form occurs in late examples, it is usually termed the Indian Bacchus. Many busts of this kind occur, as also many examples in relievo. Later he was represented as a young man with an effeminate face (θηλύμορφος, Bacch. 353; Euseb. 'Chron.' p. 29), with long blond hair (Bacch. 455, 'Cycl.' 63), with a fillet on his head (Strabo, xv. p. 1038), or an ivy crown ('Cycl.' 593), with a long purple robe and a nebris (deer-skin), and with a thyrsus in his hand.



[The Youthful Dionysus attended by a Faun, from a bas-relief in the British Museum.]

The Greek Dionysus seems to have been confounded by the Roman poets with Liber, an early Italian deity, who presided over the cultivation of corn and the wine, and who was associated with the worship of a female deity Libera and Ceres. Libera came, therefore, according to the Roman custom of uniting a female with a male divinity [BELLONA], to be regarded as the feminine counterpart of Bacchus; and instances occur where they are represented united in one figure.



[Bacchus and Libera, from the British Museum.]

Bacchus is also spoken of by Roman poets, and occasionally represented by sculptors, as androgynous, or partaking in himself of both sexes. But a clearer notion will be obtained of the artistic idea of Dionysus and his associates from a visit to the British Museum, than from any description within the narrow limits of a cyclopædia. In the Second Græco-Roman Saloon will be found a number of Bacchic representations, arranged together under the title of the Dionysiac Cycle, including statues, busts, and masks of Dionysus, both bearded and youthful; groups of the god and various personages; statues of Libera, Pan, Fauns, Satyrs, and Bacchantes, with relievi of Dionysian processions, &c., while in the magnificent collection of fictile vases in the Vase Rooms are numerous paintings of scenes from the Dionysia.

DIOPTRICS. [OPTICS; REFRACTION.]

DIORAMA, from the Greek word διορᾷν, to see through, a mode of painting and scenic exhibition invented by two French artists, Daguerre and Bouton, which, although it does not possess some of the advantages of the panorama, produces a far greater degree of optical illusion, and is therefore much better adapted for architectural and interior views. The peculiar effect of the diorama arises, in a considerable measure, from the contrivance employed in exhibiting the painting, which is viewed through a large aperture or proscenium. Beyond this opening the picture is placed at such a distance that the light is thrown upon it, at a proper angle, from the roof, which is glazed with coloured glass, and cannot be seen by the spectator. Besides the light being thus concentrated upon the picture, the effect is materially increased by the spectator being in comparative darkness, receiving no other light than what is reflected from the surface of the painting itself, and sitting at some distance from the picture. The contrast occasioned by confining the light to the picture, and the exclusion of all other objects of vision, save those represented in the painting, so that the eye has no immediate standard of comparison between them and real ones, give to this species of exhibition so much force that a very moderate degree of light will suffice to show the painting. Hence the light may be diminished or increased at pleasure, and that either gradually or suddenly, so as to represent the change from ordinary daylight to sunshine, and from sunshine to cloudy weather, or to the obscurity of twilight; also the difference of atmospheric tone attending them. These transitions, in regard to light and atmospheric effects, are produced by means of different folds or shutters attached to the glazed ceiling, which are so contrived that they may be immediately opened or closed to any extent, thereby increasing or diminishing the light just as required, and otherwise modifying it. Further than this, some parts of the painting itself are transparent, and on them the light can occasionally be admitted from behind, thereby producing a brilliancy far exceeding that of the highest lights of a picture upon an opaque ground, which can be made to appear vivid and sparkling only by contrast, not by any positive increase of light on those parts of the surface. The combination of transparent, semi-transparent, and opaque colouring, still further assisted by the power of varying both the effects and the degree of light and shade, renders the diorama, in competent hands, perhaps the most perfect scenic representation of nature, and adapts it peculiarly for moonlight subjects, or for showing such *accidents* in the landscape as sudden gleams of sunshine and their disappearance, as well as for architectural interiors. The diorama was exhibited first at Paris in 1822, and then in London in 1823, where a spacious building was erected for the purpose in the Regent's Park: but here, though at first very successful, it after a time ceased to attract, and was discontinued, and the building was converted into a Baptist chapel.

DIOSMIN. A non-azotised bitter matter found in the leaves of the *Diosma crenata*. Its composition is not known.

DIP; DIPPING NEEDLE. [MAGNETISM.]

DIPHENINE ($C_{24}H_{12}N_4$). A yellow crystalline alkaloid derived from *benzole*.

DI-PHENYL, a double prefix, used in organic chemistry to denote the presence of two equivalents of phenyl in the body to which it is immediately attached: thus *diphenyl-carbamide* signifies carbamide containing two equivalents of phenyl. Any chemical substance the name of which begins with this prefix, and which is not found in its alphabetical position, will, if of any importance, be found described under the name without one or both of the prefixes: thus, *diphenyl-oxamide* will be found described either under PHENYL-OXAMIDE or OXAMIDE.

DIPHTHERITE or DIPHTHERITIS (from διφθέρα, a skin or membrane), a term applied by M. Bretonneau and other French writers to a peculiar inflammation of the mucous membrane of the throat or pharynx, which is accompanied by the production of a false membrane. This disease first attracted attention at Tours in France, where it prevailed as an epidemic in 1818. It subsequently appeared in other towns in France, and alarmed the inhabitants of Boulogne in 1856. It has also been seen in India since its discovery and description by Bretonneau. No cases seem to have been accurately observed in this country till 1857; but since that time it has broken out in many parts of England, and presented its most characteristic symptoms. When this disease was first described, it was regarded by some writers in this country as a variety of croup, and by others as a form of scarlet fever. Now that it has appeared, few observers could be found who would not agree that it is a disease *sui generis*. The invasion of this disease has been looked on with greater anxiety, as there seems to be little doubt of its belonging to the contagious or communicable class. It is also very fatal, and already a large amount of mortality has been caused by it in this country.

The distinguishing feature of this disease is the formation of a false membrane upon the surface of the mucous membrane of the fauces. This membrane is of a whitish or ash gray colour, and frequently extends forwards from the pharynx and tonsils to the soft palate and into the nostrils, and backwards into the œsophagus. It is seldom found in the larynx and the trachea, and in this respect it differs from croup, and may be easily distinguished from it. When the membrane is found in the larynx or trachea, it is always subsequent to its appearance in the fauces, and in these cases it is most fatal. At the commencement of the disease, the membrane is seen in the form of a white spot on the pharynx or tonsils, from which it gradually extends all around. As it goes on, the membrane comes away in spots or presents fissures, through which the mucous membrane may be seen of a deep red or even of a purplish and claret colour. During the progress of the disease the cervical and submaxillary glands become swollen, and there is a fetid discharge from the nose and mouth. As the sloughs separate from the fauces, hæmorrhage frequently occurs.

The general symptoms are those of low fever. The disease sets in with shivering and intense depression, there is dryness and tingling of the throat and ears, difficulty of swallowing, vomiting, and very frequently headache. The tongue is loaded, the pulse is frequent and feeble. In the early stages it might be taken for scarlet fever. But there is no active fever, no eruption of the skin, no redness of the papillæ of the tongue, and when the patient recovers, no desquamation of the cuticle, as is constantly the case in that disease.

The prognosis in these cases is unfavourable. This disease generally terminates life by extending to the air passages and producing effusion in the glottis, which speedily terminates life.

This disease is from the beginning attended with a great depression of the vital powers, and its treatment demands that the vital processes should be sustained. A purgative may be given at the onset, but in most cases wine may be administered from the commencement of the attack. Many writers also speak highly of the chlorate of potash administered in the same way as in scarlet fever. To this may be added the preparations of ammonia. Quinine has also been highly commended, with the mineral acids. Many writers speak highly of the tincture of the sesquichloride of iron. The throat also requires local treatment. Two remedies have been generally employed, nitrate of silver and chlorine. The nitrate of silver is applied in the proportion of one drachm to an ounce of water on a sponge several times in the course of a day. Dr. Watson recommends injecting the nares with a solution of chlorine in water. This relieves the fetid smell which is very disagreeable to the patient and those around. The chlorate of potash may also be given in a linctus to lubricate the fauces, and when swallowed to act on the system.

Although this disease appears to arise where local causes predispose individuals to its occurrence, there can be no doubt that it is a communicable disease. It frequently goes through a whole family, attacking young and old. This is more especially the case in houses where the ventilation is bad, and where the drains and water-closets have been neglected. It seems especially active in houses with unemptied cess-pools and undrained privies. The disease is, however, communicated to those beyond these influences, and in many instances nurses and medical men have been attacked with the disease after attendance upon those who are afflicted with it. When the disease breaks out, the rest of the family should be removed from the house, and its sanitary condition attended to.

DIPHTHONG (*δίφθογγος*) is the sound of two vowels pronounced in rapid succession, as the German *au* in *maus*, pronounced precisely like the English word *mouse*, the vowel sound consisting of the broad *a* of *father*, followed quickly by the sound of *u* or *oo*. Again, the *i* in the English word *mind*, though represented by a single character, is virtually a diphthongal sound, consisting of the broad *a* of *father*, followed by the vowel sound which is heard in *mean*. The name diphthong however is commonly given to any vowel sound represented by the junction of two vowels, as in *dream*, though the sound produced is not compounded.

All diphthongs are said to be long syllables; and this would be true if they were only employed to mark the union of two vowel sounds. This probably was originally their sole office; for in many English words now written with diphthongs, but pronounced as if they had single vowels, an earlier pronunciation contained the double sound; and indeed this view is often supported by the provincial pronunciation of a word. For example, such words as *meat*, *dream*, *boat*, are pronounced in many parts of England as disyllables, *meät*, *dreäm*, *boät*. In practice however a diphthong is often used where the vowel sound is not only uncompounded but short, as in *friend*, *breadth*.

Again, diphthongs are occasionally used to represent simple sounds intermediate between the vowels, as in the English word *cough*, the French *fait* and *au*, and the German sounds represented by *ae*, *oe*, *ue*, commonly written *ä*, *ö*, *ü*, where the dots placed over the vowels are merely a corruption of the letter *e*.

DIPLOMACY is a term used either to express the art of conducting negotiations and arranging treaties between nations, or the branch of knowledge which regards the principles of that art and the relations of independent states to one another. The word comes from the Greek diploma, which properly signifies anything doubled or folded, and is more particularly used for a document or writing issued on any more solemn occasion, either by a state or other public body, because such writings, whether on waxen tablets or on any other material, used anciently to be made up in a folded form. The principles of diplomacy, of course, are to be found partly in that body of recognised customs and regulations called public or international law, partly in the treaties or special compacts which one state has made with another. The superintendence of the diplomatic relations of a country has been commonly entrusted in modern times to a minister of state, called the Minister for Foreign Affairs, or, as in England, the Secretary for Foreign Affairs. The different persons permanently stationed or occasionally employed abroad, to arrange particular points, to negotiate treaties commercial and general, or to watch over their execution and maintenance, may all be considered as the agents of this superintending authority, and as immediately accountable to it, as well as thence deriving their appointments and instructions. For the rights and duties of the several descriptions of functionaries employed in diplomacy, see the articles AMBASSADOR; CHARGÉ D'AFFAIRES; CONSUL; ENVOY.

DIPLOMATICS, from the same root, is the science of the knowledge of ancient documents of a public or political character, and especially of the determination of their authenticity and their age. But the adjective, diplomatic, is usually applied to things or persons connected, not with diplomatics, but with diplomacy. Thus by diplomatic proceedings we mean proceedings of diplomacy; and the *corps diplomatique*, or diplomatic body, at any court or seat of government, means the body of foreign agents engaged in diplomacy that are resident there.

Among the most important works upon the science of diplomatics are the following: Wicquefort's 'L'Ambassadeur et ses Fonctions,' 1764; Count Garden's 'Traité complet de Diplomatie, par un Ancien Ministre,' 1833; Winter's 'Système de Diplomatie,' 1830. Among the works relating to diplomacy is the collection of treatises by G. F. von Martens, continued by C. von Martens, Koch, Schöll, Klüber, and P. A. G. von Meyer.

DIPPEL'S OIL. Synonymous with *bone oil*. [BONE LIQUOR.]

DIPTERAL. [GRECIAN ARCHITECTURE.]

DIRECT and RETROGRADE, two astronomical terms, the former of which is applied to a body which moves in the same direction as all the heavenly bodies except comets; the second to one which moves in a contrary direction. The motions of the planets round the sun, of the satellites round their primaries, and of the bodies themselves round their axes, all take place in one direction, with the exception only of the comets, of which about one-half the whole number move in the contrary direction. The course of these celestial motions is always from west to east, which is the *direct* course. The *retrograde* is therefore from east to west. The real diurnal motion of the earth being direct, the apparent motion of the heavens is retrograde, so that the orbital motion of the sun and moon has, so far as it goes, the effect of lessening the whole apparent motion: or these bodies appear to move more slowly than the fixed stars. With regard to the planets, the effect of the earth's orbital motion combined with their own, makes them sometimes appear to retrograde more in the day than they would do from the earth's diurnal motion only. [PLANETARY MOTIONS.] In the Latin of the 17th century, the direct motion is said to be *in consequentia*, and the retrograde *in antecedentia*. The most simple way of remembering direct motion, is by recalling to mind the order of the signs of the zodiac. From Aries into Taurus, from Taurus into Gemini, &c., up to from Pisces into Aries, is direct motion; while from Taurus into Aries, from Aries into Pisces, &c., is retrograde motion.

DIRECTION, a relative term, not otherwise definable than by pointing out what constitutes sameness and difference of direction. Any two lines which make an angle point in different directions; a point moving along a straight line moves always in the same direction. Permanency of direction and straightness are equivalent notions. A body in motion not only changes its direction with respect to other bodies, but also the direction of other bodies with respect to it.

The most common measure of direction, for terrestrial purposes, refers to the north as a fixed direction, and uses the points of the compass. But any line whatever being drawn from the point of view, the directions of all other points may be estimated by measuring the angles which lines drawn from them to the point of view make with the standard line.

When a point describes a curve, it cannot at any one moment be said to be moving in any direction at all; for upon examining the basis of our notion of curvature, we find that it consists in supposing a line to be drawn, no three contiguous points of which, however near, are all in the same straight line. But this is a mathematical notion, which is contradicted in practice by any attempt at a curve which we can make on paper. For it is found that, as must be the case from the proposition mentioned in the article ARC, when two points of a curve are taken very near to each other, and joined by a chord, the widest interval between the chord and the arc disappears or becomes imperceptible long before the chord and arc disappear. Hence arises the notion that a curve may in fact be composed of very small straight lines, each of which has of course a definite direction. But though such notion must be abandoned in geometry, yet it leads to the stricter notion of a TANGENT [see also CONTACT], or of a straight line of which, as soon as the term is explained, we unhesitatingly admit,—1, that if a line moving on a curve be said to have a direction at all at any point, the direction must be that of a tangent at that point; 2, that it is highly convenient to say that a point moving in a curve is moving in a *continually varying* direction. Here, as in other cases [VELOCITY; CURVATURE; &c.], we obtain exactness by making definitions drawn from the inexactness of our senses apply, not to the notions which first gave them, but to the final limit towards which we see that we should approach if our senses were made more and more exact, but which, at the same time, we see that we should never reach as long as any inexactness whatsoever remained.

DIRECTOIRE EXECUTIF was the name given to the executive power of the French republic by the constitution of the year 3 (1795), which constitution was framed by the moderate party in the National Convention, or Supreme Legislature of France, after the overthrow of Robespierre and his associates. [COMMITTEE OF PUBLIC SAFETY.] By this constitution the legislative power was entrusted to two councils, one of 500 members, and the other called "des anciens," consisting of 250 members. The election was graduated; every primary or communal assembly chose an elector, and the electors thus chosen assembled in their respective departments to choose the members for the legislature. Certain property qualifications were requisite for an elector. One-third of the councils was to be renewed every two years. The Council of Elders, so called because the members were required to be at least forty years of age, had the power of refusing its assent to any bill that was sent to it by the other council. The executive power was entrusted to five directors chosen by the Council of Elders out of a list of candidates presented by the Council of Five Hundred. One of the five directors was to be changed every year. The directors had the management of the military force, of the finances, and of the home and foreign departments; and they appointed their ministers of state and other public functionaries. They had large salaries, and a national palace, the Luxembourg, for their residence, and a guard. The history of the events which took place during the four years of its existence will be found under BARRAS, and BONAPARTE, NAPOLEON, in the BIOG. DIV.

DIRECTRIX. (*Linea directrix*, a directing line.) This term is applied to any line (straight or curved) which is made a necessary part of the description of any curve, so that the position of the former must be given before that of the latter is known. Thus in the question, "required the curve described by a point in a straight line the two ends of which must be on two fixed straight lines," the two fixed lines are directrices. Custom has sanctioned the special application of this term to lines connected with a few curves, and particularly with the ellipse, hyperbola, parabola, and conchoid of Nicomedes. But in reality, with the exception of the circle, there can be no curve which is without one or more lines to which the name of directrix might be given.

DIRGE, in music, a hymn for the dead, a funereal song. This word is a contraction of *Dirige*, the first word of the antiphona, "Dirige, Domine Deus," chanted in the funeral service of the Roman Catholic Church. The abbreviation seems to have crept into use about the middle of the 16th century.

DISABILITY (Law), an incapacity in a person to inherit lands or enjoy the possession of them, or to take that benefit which otherwise he might have done, or to confer or grant an estate or benefit on or to another. All persons who are disabled from taking an estate or benefit are incapable of granting or conferring one by any act of their own, but many persons who are by law incapable of disposing of property may take it either by inheritance or gift.

Disability is ordinarily said to arise in four ways: By the act of the ancestor; by the act of the party himself; by the act of the law; or by the act of God.

By the act of the ancestor, as where he is attainted of treason or murder, for by attainder his blood is corrupted, and his children are made incapable of inheriting. But by the stat. 3 & 4 Will. IV., c. 106, § 10, this disability is now confined to the inheriting of lands of which the ancestor is possessed at the time of attainder; in all other cases a descent may be traced through him.

By the act of the party himself, as where a person is himself attainted, outlawed, &c., or where, by subsequent dealings with his estate, a person has disabled himself from performing a previous engagement, as where a man covenants to grant a lease of lands to one, and, before he has done so, sells them to another.

By the act of law, as when a man, by the sole act of law without any default of his own, is disabled, as an alien born, &c.

By the act of God, as in cases of idiotcy, lunacy, &c., but this last is properly a disability to grant only, and not to take an estate or benefit —for an idiot or lunatic may take a benefit either by deed or will.

There are also other disabilities known to our law, as infancy, and coverture; but these also are confined to the conferring of interests.

Married women, acting under and in conformity to POWERS, and formerly by fine, but, since the 3 & 4 Will. IV., c. 74, by deed executed under the provisions of that statute, may convey lands; and infants, lunatics, and idiots, being trustees, and not having any beneficial interest in the lands vested in them, are by various statutes enabled to dispose of them under the direction of the Court of Chancery.

Particular disabilities also are created by some statutes; as, for instance, Roman Catholics, by the 10 Geo. IV., c. 7 (the Emancipation Act), are disabled from presenting to a benefice; and foreigners (although naturalised) cannot hold offices, or take grants of land under the crown. [DENIZEN.] (Cowel's 'Interp.;' 'Termes de la Ley.')

DISACRYL. An isomeric modification of ACROLEIN.

DISBUDDING, in horticulture, consists in removing the buds of a tree before they have had time to grow into young branches. It is a species of pruning which has for its object not only training, but also economy with regard to the resources of a tree, in order that there may be a greater supply of nourishment for the development of those buds which are allowed to remain.

If the roots are capable of absorbing a given quantity of nutritive matter for the supply of all the buds upon a stem, and if a number of those buds be removed, it must be evident that those which remain will be able to draw a greater supply of sap and grow more vigorously than they otherwise would have done. This fact has furnished the idea of disbudding.

This kind of pruning has been chiefly applied to peach and nectarine trees, but the same principle will hold good with all others of a similar description, and might be practised upon them if they would repay the labour so expended.

The French gardeners about Montreuil and in the vicinity of Paris have carried this practice to a great extent, and with considerable success.

Several of their methods have been described by Dr. Neill, the secretary of the Caledonian Horticultural Society, in his horticultural tour. In one of them, termed *à la Sieulle*, and invented by Sieulle, gardener at Vaux Praslin, near Paris, the training is made to depend entirely upon the exactness of disbudding.

The peculiarity of Sieulle's method is as follows:—After the stock has been budded, two branches are trained at full length to a trellis or wall: late in autumn or in winter all the buds, with the exception of four on each shoot, are neatly cut out, or disbudded; these four in their turn form shoots in the succeeding summer, which are cut down to about one-third of their length in autumn, and also disbudded in the same manner as the two principal branches of the preceding year. This kind of pruning being always performed prevents a superfluous development of buds and the consequent necessity of cutting them out as branches in the following season. Du Petit Thouars, whose opinions are entitled to much respect, passes a high eulogium upon this system of Sieulle: he says, "by this method the young tree is more quickly brought to fill its place upon the espalier; it is afterwards more easily kept in regular order: many poorer flower-buds are allowed to develop themselves, but the necessity of thinning the fruit is thus in a great measure superseded, and the peaches produced are larger and finer."

Dumoutier's system of disbudding is somewhat different from that of Sieulle. Instead of performing this operation late in the autumn, he defers it until spring, when the buds are unfolded: all those upon the young shoot of the previous year, with the exception of the lowest and the one above the highest blossom, are then carefully removed; of the two which are left, the first is termed the *bourgeon de remplacement* for the next year, and the latter is allowed to remain to draw up the sap for the maturing of the fruit. This method of pruning, as far as disbudding is concerned, is precisely the same as that practised by Seymour, of Carleton Hall, in England.

It must not be thought, however, from this statement that the training of Dumoutier and Seymour is the same, or that their trees assume precisely the same appearance: for example, Dumoutier's branches proceed from two principal arms, Seymour's from one in the centre: in the system of the former, the fruit-bearing branches are on both sides of the old wood; while in that of the latter they are only allowed to grow from the upper sides.

Disbudding in spring is frequently and beneficially practised by many intelligent gardeners, both in England and Scotland, upon English fan-trained peach-trees, with a view to thinning the young wood, taking care to leave enough for the production of fruit in the following year.

When spurious buds can be removed from peach or nectarine trees before development, with the certainty of those succeeding which are allowed to remain, it must be of material consequence, as the latter will not only be better supported, but will also receive a greater quantity of light, so essential to mature and ripen the young wood. Unfortunately, however, Sieulle's plan cannot be practised with any degree of success in England; those buds which are left, and upon which so much dependence is placed, often do not grow; a vacancy is the consequence, and the tree is deformed. The climate of Montreuil is much more favourable to the growth of the peach-tree than that of Britain; and although the winters of Paris are severe, yet the mean degree of summer heat is much greater there than in any part of England; and perhaps the peculiar nature of the soil renders peach-trees much more yielding to art there than in this country.

For these reasons, however useful the plan of disbudding in autumn or winter may be in the gardens of France, it would be improper to practise it to any extent in those of England.

It has, however, been proved that a judicious thinning of the buds after they have been unfolded in spring (when an experienced individual can foresee the strength of those which he is about to leave, and to which he looks for his fruit in the following year), is of great utility.

DISC (*discus*, δίσκος), is used for the face of a circular plate, and frequently for a thin plate of any substance. Thus we speak of the sun's disc (referring to the appearance of the sun), and also of a disc of metal.

DISCIPLINE, MILITARY, the series of duties which are to be performed by military men. It also signifies a conformity to the regulations by which those who serve in the army are governed in all matters relating to the practice of their profession.

DISCLAIMER. A plea by a tenant in any Court of Record in which he disclaims to hold of his lord, which operates as a forfeiture of the lands to the lord upon reasons most apparently feudal. So if the tenant does any act which amounts to a disclaimer, as if he claims a greater estate than was granted to him, or affirms the reversion to be in a stranger, such behaviour amounts to a forfeiture The writ of right sur disclaimer was the old form in which the lord took advantage of the forfeiture; but as it was decided that the tenant might be treated as a trespasser, and that notice to quit was not necessary, the more convenient action of ejectment came into use, and the proceeding by writ of right was ultimately abolished.

One of the pleadings in a suit in Chancery is also called a disclaimer, as where a defendant, in his answer to the complainant's bill, disclaims all interest in the matter in question. [EQUITY.]

And where an estate is given either by deed or will to a person, he may by deed (which need not be enrolled, or, as it is called, made matter of record) disclaim all interest thereunder.

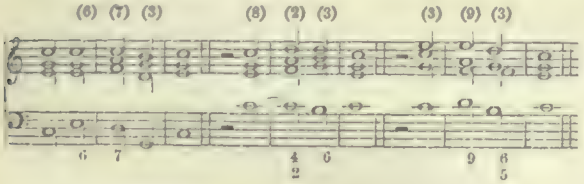
An executor is said to disclaim when he renounces probate of the will of his testator; and where the will contains a devise of lands to the executor, the disclaimer ought to be made by deed to afford evidence, in deducing a title to the lands, of the fact of disclaimer.

DISCONTINUITY (Algebra, &c.). Continuous changes are those which are so made that no two states exist without every possible intermediate state having been in existence between them. Thus the square on a line of 4 inches contains 16 square inches, while that on a line of 5 inches contains 25 square inches; and there is no possible area between 16 and 25 square inches which is not equal to the square described on some line between 4 and 5 inches. That is, if a straight line increase continuously, the square described on it increases continuously.

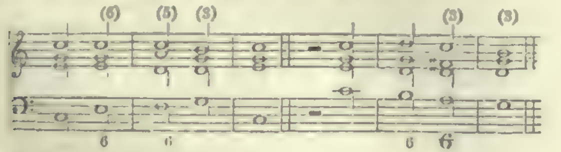
The first introduction of discontinuity arises from the attempt to represent all magnitudes by numbers. Arithmetical symbols cannot represent continuous change of magnitude. If a foot be divided into 2, 3, 4, &c., equal parts, and so on *ad infinitum*, there exist infinite numbers of lengths which will not be represented by any whatsoever of the resulting fractions of a foot. Hence the difficulties of INCOMMENSURABLE magnitudes, which arise from the failure of the attempt to represent flowing or continuous changes by the means of changes which always suppose finite intervals, as in passing from number to number.

But the arithmetical difficulty, being introduced antecedently to the express consideration of discontinuity, is rarely treated as belonging to this subject. In the higher parts of mathematics the necessity for the consideration of discontinuous expressions began with the investigation of partial differential equations. In the introduction of the arbitrary functions which those equations require, discontinuous functions were thought to be admissible by Euler, an opinion which was controverted by D'Alembert, and supported, conclusively, it has always been thought, by Lagrange. It is our own opinion that not only the arbitrary function of a partial equation, but even the arbitrary constant of a common equation, may be allowed to be discontinuous, unless the contrary be a condition of the problem, expressed or implied. By a discontinuous constant, we mean one which preserves one value between certain limits of the value of the variable, which then suddenly changes its value, preserving the new value till the variable attains another limit, and so on.

DISCORD, in music, a sound which, when heard with another, is disagreeable to the ear, unless treated according to the rules of art. Discords are the 2nd, sharp 4th (tritonus), flat 5th (semidiapente), minor or flat 7th, and major or sharp 7th. The ratios of these are 9 : 8, 45 : 32, 64 : 45, 9 : 5, and 15 : 8. The 9th (9 : 4) is also a discord, and though only the octave to the 2nd, is considered in harmony as a very different interval, and treated in a different manner. The 4th (4 : 3) is either discord or concord, according to the manner in which it is accompanied. [CONCORD.] Discords commonly, but not always, are *prepared*, that is, the note which is to become the discord, is first heard as a concord: and their *resolution* is absolutely necessary; that is, the discord must pass into a concord, though the resolution is occasionally retarded. Examples :—



The perfect 5th in the chord of $^6_5$, and the 3rd in the chord of $^6_4$, are treated, so far as regards resolution, as discords. Examples :—



DISCOUNT, a sum of money deducted from a debt in consideration of its being paid before the usual or stipulated time. The circumstance on which its fairness is founded is, that the creditor, by receiving his money before it becomes due, has the interest of the money during the interval. Consequently, he should only receive so much as, put out to interest during the period in question, would realise the amount of his debt at the time when it would have become due. For instance, 100*l.* is to be paid at the end of three years, what should be paid now, interest being 4 per cent.? Here it is evident that if we divide the whole debt into 112 (or 100 + 3 × 4) parts, 100 of these parts will make the other 12 in three years (at simple interest), whence the payment now due is the 112th part of 10,000*l.*, or 89*l.* 5*s.* 9*d.* The rule is, n being the number of years (or fraction or number and fraction), r the rate per cent., and D the sum due,

$$\text{Present value} = \frac{100\,\mathrm{D}}{100+nr}; \text{ discount} = \frac{\mathrm{D}\,n\,r}{100+nr}.$$

In practice, it is usual not to find the real discount, but to allow interest on the whole debt in the shape of abatement. Thus it would be considered that, in the preceding example, three years' discount upon 100*l.* at 4 per cent. is 12*l.*, or 88*l.* would be considered as the present value.

In transactions which usually proceed on compound interest, as in valuing leases, annuities, &c., the principle of discount is strictly preserved. The present value in the preceding case is, in its most usual form,

$$\frac{\mathrm{D}}{(1+\rho)^n}, \text{ and the discount } \mathrm{D} - \frac{\mathrm{D}}{(1+\rho)^n};$$

where ρ is the rate per pound (not per cent.: thus it is ·04 for 4 per cent.). But recourse is usually had to the tables of present values which accompany all works on annuities or compound interest. [INTEREST.]

The name of discount is also applied to certain trade allowances upon the nominal prices of goods. In some branches of trade these allowances vary according to the circumstances which affect the markets, and what is called discount is in fact occasioned by fluctuations in prices which it is thought convenient to maintain nominally at unvarying rates. This system is practised in some branches of wholesale haberdashery business, and we have seen a list of prices furnished to his customers by a manufacturer of tools at Sheffield, in which the nominal price of each article was continued the same at which it had stood for many years, while to every different species of tool there was applied a different and a fluctuating rate of discount, this fluctuation constituting in fact a difference of price between one period and another: the rates of discount in this list varied from 5 to 40 per cent. upon the nominal prices of the different articles.

The term discount is also employed to signify other mercantile allowances, such for example, as the abatement of 12 per cent. made upon the balances which underwriters, or insurers of sea risks, receive at the end of the year from the brokers by whom the insurances have been effected. The word discount is further used, in contradistinction to premium, to denote the diminution in value of securities which are sold according to a fixed nominal value, or according to the price they may have originally cost. If, for example, a share in a canal company upon which 100*l.* has been paid is sold in the market for 98*l.*, the value of the share is stated to be at 2 per cent. discount.

There are one or two old difficulties connected with discount. The first is that of the *equation of payments*. Were it not for the difficulty, and its principle, this would not be worth notice. It was at one time the custom of the works on arithmetic to point out, when sums of money are due at different times, at what time the total amount is to be paid at once, in such manner that the receiver may gain, by the sums which are prepaid, what he loses by those which are overdue.

To take a simple case, say it is understood that money makes 5 per cent. simple interest, that 100*l.* is due in three years, and 300*l.* more in seven years. The first rule that was given leads, as the reader knows, to the payment of the whole 400*l.* in six years; by which the interest on 300*l.* paid a year before its time balances that on 100*l.* paid three years after its time. But this, it is said, was not fair; for not interest, but discount, should be allowed for the sum paid before it is due. That is, the 400*l.* paid at the intermediate time should yield 100*l.* due + interest on it since it was due + a sum which put out to interest will make the 300*l.* at the end of the seven years. The rule for this case gives a result 5·9615574 years, instead of six years; which will be found to satisfy the conditions.

In truth, however, it depends entirely upon what the notion of fairness is, whether one rule is better than the other, or whether either will do. And it must be remembered that *simple interest* is a fiction in real business. A creditor cannot demand more than simple interest by law: but it does not therefore follow that because certain money is paid under the name of interest, the receiver will let it lie barren in a bag. But what we say is this: *keep to the fiction* on which both rules are constructed, *let all interest-money remain barren*, and the two rules will come to the same thing in the end. And it is not fair to construct rules on the supposition of simple interest, and then to complain of the inaptitude of those rules to represent the results of real business. Remaining by simple interest, let us see how the receiver will stand at the end of the seven years, upon the different suppositions :—

1. If no equation of payments be made, he will have 100*l.* + four years' interest + 300*l.* just received, 420*l.* in all, with which he is to go on making interest on 400*l.* only.

2. If he receive by the first rule 400*l.* at the end of six years, he will at the end of the seventh year have 420*l.*, of which 400*l.* is to go on at interest as before.

3. If he receive by the second rule he will have at the end of the seventh year (100*l.* + 2·961... years' interest) which he received + 1·038... years' interest which he makes on the 100*l.* (the other part not making interest) + the sum which will in 1·038... years yield 300*l.* (285·19*l.*...) + the interest on this. That is, 420*l.* altogether, of which 20*l.* is interest only : for the last-mentioned item, though gained in the manner of interest, is discount intended to make up a *principal.* Or, if any one will not admit this last distinction, then the most approved rule puts the receiver in a worse position than the old rule.

The fact is, that if equation of payments were ever made, it ought to be supposed that all money, principal and interest, becomes productive money to the receiver from the moment it is received : or compound interest should be supposed. This puts the parties into a state of equity at all times, both during the longest term of debt and after. To show this, suppose that A is due at the end of a years and B at the end of b years, interest being r per pound. To satisfy this debt by a sum A + B paid at x years from this time, the equation to determine x is

$$\mathrm{A}+\mathrm{B}=\mathrm{A}(1+r)^{x-a}+\frac{\mathrm{B}}{(1+r)^{b-x}}$$

and the receiver of the equated sum, m years after its receipt, or $x+m$ years from the present time, will have $(\mathrm{A}+\mathrm{B})\ (1+r)^m$ which is

$$\mathrm{A}(1+r)^{x+m-a}+\mathrm{B}\frac{(1+r)^m}{(1+r)^{b-x}}$$

Or

$$\mathrm{A}(1+r)^{x+m-a}+\mathrm{B}(1+r)^{x+m-b}$$

And this is precisely what he would have had from the payments themselves. And the accumulations or present value of the equated sum are at all times equal to the accumulations or present values of the payments.

There is another remarkable case of the same kind, in which discount at simple interest is compared with notions derived from compound interest, and a rule is consequently said to be false which is, upon its own hypothesis, perfectly true. The value of an interminable annuity, calculated at simple interest, comes out infinitely great : or no sum is large enough to pay it. Now it is clear that 20*l.* will pay an annuity of 1*l.* a year at five per cent. for ever. And this may even be called simple interest, for at the end of a year the interest of the 20*l.* is paid away, and the original principal only remains : so that there is no interest upon interest. But the truth is, that in the construction of all rules at simple interest, the money is arbitrarily divided into two parts, productive and unproductive, and a rule which expressly requires payment to be made from time to time out of the productive part, may produce very different results from another in which the unproductive part is paid away first. Now take the case of an annuity for three years, of 1*l.*, money making r per pound. The ordinary rule gives

$$(1+r)^{-1}+(1+2r)^{-1}+(1+3r)^{-1}$$

At the end of a year, this becomes

$$1+\frac{1+r}{1+2r}+\frac{1+r}{1+3r}$$

The first term 1 is partly principal, partly interest : and 1*l.* of annuity has become due. But the manner in which the rule was framed does not allow us to pay away the $r(1+2r)^{-1}$ and $r(1+3r)^{-1}$, which are never to make interest again, in part of the first year's annuity, but requires that the 1, part of which will make interest, should all be so paid. And, when the productive money is broken in upon before the unproductive is all gone, it is perfectly true that no sum is large enough to pay a perpetual annuity : and, if this be done, not only may the rule for a perpetual annuity be objected to, but with as much justice that for a finite term of years. For instance, at 10 per cent., an annuity of 1*l.* for five years is worth, according to the usual simple-interest suppositions, 3·89261*l.* A year's interest is ·389261*l.*; let this all be paid away, and the balance of 1*l.* made up out of the principal, and so on, and it will be found that there is a sum in hand at the end of the ten years : in fact 3·79079*l.* will in this way be enough to meet all demands. But the manner in which the rule is constructed supposes the annual demands to be made up out of principal and interest in the following way, the sums before the lines showing how the pound yearly accruing due is raised, partly out of principal, partly out of interest :—

	Principal.		Interest.	
	3·89261		·38926	
Pay	·90909	+	·09091	= £1.
	2·98352		·29835	
			·29835	
Pay	·83333	+	·16667	= £1.
	2·15019		·43003	
			·21502	
Pay	·76923	+	·23077	= £1.
	1·38096		·41428	
			·13810	
Pay	·71429	+	·28571	= £1.
	·66667		·26667	
			·06667	
Pay	·66667	+	·33333	= £1.
	·00000		·00001	

While if interest were made to go as far as it could, we should have

3·89261		
·38926		
3·28187	after paying £1.	
·32819		
2·61006	,,	,,
·26101		
1·87107	,,	,,
·18711		
1·05818	,,	,,
·10582		
·16406	,,	,

to that there would remain ·164*l.*

The truth is, that the rule for annuities by discounting at simple interest *is* wrong except upon the condition that principal and interest are to be rated in a specified way (which those who understand the formula will easily collect) to meet the accruing demands. And moreover, when interest is to be all disposed of first, before any principal is touched, *the rules for simple and compound interest are identical.*

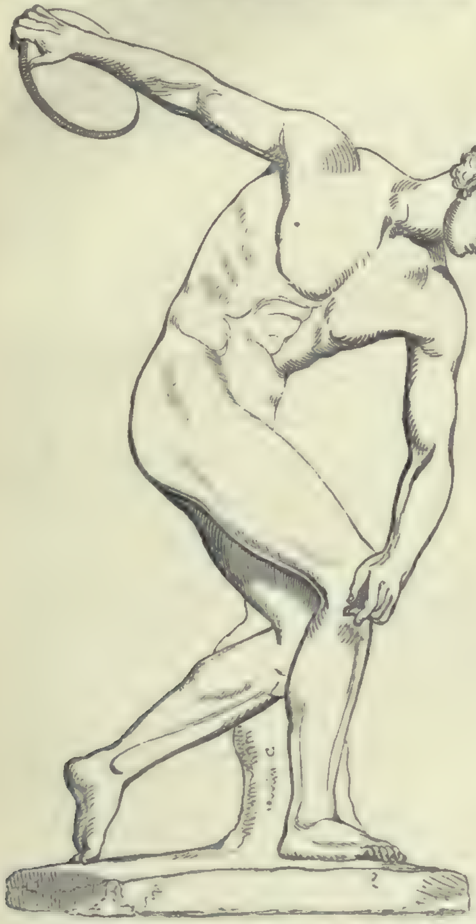
It is, however, necessary to distinguish between true discount and the discount of commerce. When a bill of exchange for 100*l.*, having three months to run, is presented by the holder for discount ; the discounter calculates the simple interest on 100*l.* for three months, with three days of grace added, deducts this from the amount of the bill and pays over the difference to the holder. Thus it will be found on consideration, that the discounter always obtains something more than the usual and current rate of interest for the money that he thus employs. Bills of exchange, on which are the best names, are discounted on the lowest or most liberal terms ; because the rate of discount must, of course, rise as the character of the parties to the bill appears to be lower in point of solvency : the rate of discount also has a tendency to rise, when money is scarce, which tendency not unfrequently grows into an effect almost independently of the character of the paper offered for discount. [See examples under BANK ; where also see Re-discount, vol. i., col. 858. The usual course of the Bank of England in regard to discounting will be found fully explained in the article BANK, BANKER, BANKING.] Also, under other circumstances, when confidence is interrupted, the discounting of bills is only done at very high rates, and in some extreme cases it is altogether refused by the ordinary bill discounters. ('Rep. of Committee on Bank Acts' 1858, p. viii.)

Discount is also said to take place on merchandise, when a buyer having agreed with the seller to pay for the goods so much on such a day which is to come, before that day arrives finds that he is in cash sufficiently to pay, and claims and gets from the seller a deduction from the price so settled, in consideration of his anticipating the day of payment. This discount is in practice made at a rate which usually exceeds the current interest of the day.

DISCOVERY IN LAW. [EQUITY.]

DISCOVERY. [INVENTION AND DISCOVERY.]

DISCUS (*δίσκος, discos*), a quoit of stone, brass, or iron, 10 or 12 inches in diameter, with which the Greeks and Romans diverted themselves in the public games. The discus, when perforated like our modern quoit, was thrown by the help of a thong, put through the middle of it. It was at other times of a solid piece, and was then hurled directly from the hand. The object was to throw it to as great a distance as possible. This last method is illustrated by the celebrated statue of the Discobolus, or quoit thrower, attributed to Myron. Of this famous statue several ancient copies are in existence, one of the very finest being that in the British Museum engraved below. The figure is represented in action at the precise moment of delivering the discus. Ovid ('Metam.,' li. x., v. 175) and Statius ('Theb.,' vi., v. 646) have both described the diversion of the discus; see also Petri Fabri, 'Agonisticon, sive de Re Athletica, Ludisque Veterum,' 4to, li. ii., c. i., Lugd. 1595.



[The Discobolus, from the statue in the British Museum.]

The term discus was likewise applied to circular shields or bucklers, of a large size, placed in the temples, on which great actions were represented, or the names inscribed of the ephebi, that is of the young men, who had devoted themselves to the service of their country. One of these circular shields is in the Townley Collection of the British Museum, containing the names of the ephebi of Athens, under Alcamenes, when he held the office of cosmetes. It was found in a church at Athens in 1748, by Dr. Askew, who was informed that it had been brought there from the Parthenon. Such too was the shield of Scipio Africanus, found in the Rhone in 1656, engraved in Spon's 'Miscellanea Eruditæ Antiquitatis,' p. 152, edit. 1685. Anacreon has an ode on a disk of silver, representing Aphrodite rising from the sea: Od. 51, Εἰς Δίσκον ἔχοντα Ἀφροδίτην. See likewise Montfaucon, 'Supplem. de l'Ant. Expliq.,' liv. iii. p. 64. Discs sculptured on both sides, with heads, bacchanal subjects, &c., were also suspended by chains between the columns of Roman mansions and theatres. Several specimens of these *clypea*, as they were called, may be seen in the Græco-Roman Basement Room of the British Museum.

DIS-DIAPASON, the name given by the Greeks to a scale of two octaves. [DIAPASON.]

DISLOCATION. Various parts of the body are liable to be displaced by the direct application of violence or by more gradual causes. But the term *dislocation* is commonly appropriated to displacements occurring about the joints. In this sense it is nearly synonymous with *luxation*, but not entirely; for the latter term carries with it more of the idea of external force, and it is not quite so generally applied. It is usual, for instance, to speak of the *dislocation*, not the *luxation*, of the internal cartilage of the knee; and the latter term is seldom if ever used in describing the displacements of the small bones of the wrist or instep, or of single vertebræ.

The injuries classed under this title may be effected by external violence, or by the undue contraction of muscles, or by both of these causes combined; and they result in some instances from disease within the joints themselves, by which their ligaments are weakened or destroyed, and their sockets rendered insecure by ulceration and other gradual changes.

When, by the protrusion of the bone through the skin, or otherwise, the dislocation is complicated with an external wound exposing the cavity of the joint, it is said to be *compound;* and, as in the parallel case of fracture, this aggravation of the injury is very serious, and the most skilful management is required to save the life or limb, where the injury happens to one of the larger joints.

The particular dislocation takes its name either from the joint itself or from the farthest bone; and various terms are added to indicate the direction of the displacement, or the new situation of the head of the bone. Thus, the most common form of the accident at the hip is called "a dislocation of the head of the *femur* (thigh-bone) *backwards* upon the *dorsum ilii*" (flat part of the haunch-bone).

Any bone may be displaced in any direction, but the accident happens most frequently in those joints and directions in which the extent of motion is the greatest. Thus the most common dislocation is that of the shoulder, which is the most movable joint; and its most frequent variety is that in which the head of the *humerus* (or bone of the upper arm) is drawn downwards into the *axilla* (or arm-pit) by the sudden contraction of certain strong muscles. This happens when the arm is raised to the utmost, as in reaching to close a window; that is when it has moved through an angle of 180 degrees from its natural position. The most usual dislocation of the hip is that, already mentioned, on the *dorsum ilii*, for the same reason. It is generally produced by sudden pressure or a blow on the knee when the thigh is bent upon the abdomen; the head of the *femur* is thus driven backwards from the socket, and is then drawn farther back and upwards by the powerful muscles of the buttock.

The jaw is sometimes thrown out of joint by the mere act of yawning; and that accident happened to a gentleman known to the writer in opening his mouth to make the usual response at church. The word was cut short at the first syllable; for in such cases the chin suddenly drops and is thrown forward, and it is impossible by any effort to shut the mouth. This distressing but irresistibly ludicrous accident may be relieved immediately by any bystander wrapping a napkin round his thumbs and placing them firmly against the back teeth, so as to press them downwards, while with the fingers and palms the chin is steadily raised and pushed backwards. But the operator should be on the alert to withdraw his hands the moment the jaw snaps back into its place, or he may receive a very unpleasant intimation of the success of his efforts.

It will be easily seen from these instances how important a part is played by the muscles in determining both the occurrence and direction of these accidents. Hence arises in part their infrequency, often wondered at, during infancy and childhood; for though the flexible joints of the young have a greater extent of motion than those of the adult, their muscular power is not only weaker as compared with the strength of their ligaments, but is much more tardily thrown into action, as may be observed in their tottering gait. The fragility of their bones is another cause of this infrequency, by rendering them more liable to be broken than displaced by external violence. The only dislocation that is at all common in children is that of the hip, which is the consequence of scrofulous ulceration of the ligaments and the socket, and of the ball-shaped head of the femur within it.

The reader will be prepared by what has been said to learn that the spasmodic and violent contraction of the muscles consequent upon these displacements is the chief or only obstacle to their reduction.

This object is effected by a process technically called *extension*, consisting in the application of force in a proper direction, and steadily kept up till the muscles are fatigued. The head of the bone is thus drawn down a little below the level of the joint; and being lifted over the edge of the socket, slips easily into its place upon slightly relaxing the extending force. This force is often required to be very considerable, and in such cases it is customary to make use of a block of pullies, the bone which contains the socket having been first securely fixed to a staple in the wall by proper bandages. Luxation of the hip is here supposed; for the other joints are so inferior to that in strength that their displacements may generally be reduced by less imposing means. It is sometimes necessary to favour the relaxation of the muscles by emetics, warm baths, and bleeding, and it is reckoned a point of good management to call off the attention of the patient during the extension by annoying him with questions and even exciting him to anger.

Almost all dislocations arising from accident may be reduced in this way, and the joint rendered nearly or quite as perfect as before: but this can only be done on condition of perfect rest during a period sufficient for the firm union of the ruptured ligaments; for if this precaution be not strictly observed, and the ligaments are suffered to be stretched by motion while the uniting substance is soft and extensible, the accident is ever afterwards liable to recur. No time should be lost in seeking assistance, for the swelling that comes on soon renders the nature of the accident obscure, and the reduction extremely difficult and painful. When a joint has been unreduced for a certain time, which varies with the particular joint, and with the bodily strength of the individual—the weaker having the advantage in this respect—it is unwise to make any attempt at reduction. The parts have now become consolidated and adapted to their new situation, and either the limb is permanently fixed or a new joint is under process of formation. In the latter case the substitute is often better than might be expected; and as this curious provision of nature cannot be improved upon by art, it is better to leave it alone.

The most dangerous dislocations are those of the vertebræ or bones of the spine, because in that case all the parts of the body below the injury are paralysed. But the vertebræ are so curiously locked together, and have singly so little motion, and are at the same time so well supported by ligaments and muscles, that they are seldom dislocated unless by a force sufficient to break as well as to displace them. Such an injury is almost always fatal, and instantly so in general when it takes place above the origin of the nerves of respiration, that is, above the fourth vertebræ of the neck. The object of the executioner in hanging a criminal is to produce this effect, but he more often fails than succeeds.

DISPART, the difference between the semidiameter of the base ring, at the breech of a gun, and that of the ring at the swell of the muzzle.

On account of the dispart, the line of aim or line of metal, which is in a plane passing through the axis of the gun, always makes a small angle with the axis; so that the elevation of the latter above the horizon is greater than that of the line of aim: an allowance for the dispart is consequently necessary in determining the commencement of the graduations on the tangent scale, by which the required elevation is given to the gun.

The dispart, therefore, subtends, at the base of the gun, an angle equal to that which, in a vertical plane passing through the axis of the bore, would be contained between that axis and a line (called the *line of metal*) drawn from the circumference of the base to that of the muzzle. In a 24-pounder gun, nine feet long for example, the dispart is equal to 2·735 inches, and the angle subtended by it is equal to 27′ nearly; allowance must consequently be made for this value in pointing the gun by the line of metal.

In order to place the axis of the bore at any angle with a horizontal plane, a "tangent scale" is employed [ORDNANCE]; and in determining the graduations of this scale, it is manifest that the length of the part raised out of the groove in the base of the gun should (the length of the gun being considered as the radius) be equal to the tangent of the difference between the number of degrees in the proposed angle of elevation and the angle subtended by the dispart; in order that, on lowering the base of the gun till a line joining the top of the scale and the top of the muzzle is parallel to the horizon (which may be determined by a spirit-level on a rod laid from one of those points to the other), the axis of the bore may be correctly elevated. Thus, in the gun above mentioned, for an elevation of one degree, the scale being raised up till the division marked 1° coincides with the top of the base ring, the part raised should be equal to the tangent of 33′ only; for an elevation of two degrees, the part raised should be equal to the tangent of 1° 33′; and so on.

In some guns, however, such as the 8″ and 10″ shell guns, the 68-pounders, and some 32-pounders, where the line of metal would give a large dispart, the inconvenience arising therefrom is avoided by a dispart sight, a raised sight on the centre of the gun between the trunnions which is of such a height that the line joining its top and the notch in the base ring is parallel to the axis of the gun.

DISPENSARY, an institution supported by voluntary contributions for the supply of the poor with medical and surgical advice, and with medicines gratuitously. Institutions of this kind are of very recent origin. They differ from hospitals in this, that the sick, when too ill to attend personally at the institution, are sometimes visited at their own homes by the medical officers of the charity. Each dispensary indeed is restricted to a certain district, beyond the limits of which the patients are not visited at their own houses. To every dispensary there are always attached one, and sometimes two physicians; one surgeon, and often a consulting surgeon, and a resident medical officer who dispenses the medicines prescribed by the physicians and surgeons. Every subscriber to the institution who pays annually a certain sum is called a governor, who is entitled to have at least one patient always on the books; a person who subscribes a larger amount in one sum is called a life-governor, who may have two or more patients on the list. The medicines, which are commonly purchased in considerable quantities at a time and at wholesale prices, are dispensed in inexpensive forms, and in this manner the extent of the relief afforded is great, while the cost is trifling. No other kind of charity affords so much real assistance at so small an expense, and perhaps fewer objections apply to this than to any other mode of giving eleemosynary aid to the poor. Its peculiar excellence is that it enables the sick poor to obtain advice on the very first day of their ailment, and they are thus frequently enabled to avoid a protracted illness. Even the great metropolitan hospitals are often so full that urgent cases are constantly obliged to wait days and even weeks before admission can be obtained; but by means of the dispensary poor families, and even the heads of such families in regular employment, may procure medical and surgical assistance without leaving their occupation even for a day. It would be a great improvement in the principle of these institutions if some contribution towards their support on the part of the poor themselves were required to entitle them to avail themselves of the advantages which they afford. This would remove the only objection that can be urged against such establishments, and would enable the independent labourer, without asking charity, to procure the best advice for his sick family at a much cheaper rate than he can possibly do at present.

At the same time it should be recollected, that these institutions are exposed to much abuse. The attendance of the medical officers being gratuitous, there is a great inducement to a hasty and insufficient attendance on the sick. On the other hand, a great number of persons obtain relief at these institutions who could well afford to pay for medical attendance. The only check upon these abuses would be the payment of the medical officers for their services, who should be responsible for the proper performance of their duties to the governors. The governor too ought not to use these institutions for the benefit of his poor relations or servants, but to take care that only those who cannot afford to pay are recommended for relief. This was the principle advocated by Mr. Smith of Southam, in his self supporting dispensaries. But unfortunately it met with little support or encouragement. Many of the clubs, or societies, particularly among the Jews, are on the independent plan.

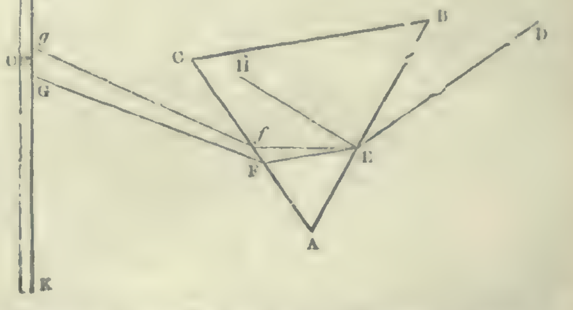
DISPENSATION. The only kind of dispensation now used is that by which the bishop licenses a clergyman within his jurisdiction to hold two or more benefices, to reside out of his parish, or dispenses with some other particular of his strict duty.

Dispensations formed a great source of the revenue of the court of Rome; for the pope's dispensations prevailed against the law of the country in many if not most instances, indeed in all of an ecclesiastical nature. This abuse was abolished in England by the statute 25 Henry VIII., c. 21; and the power of the pope to grant dispensations, not contrary to the law of God, was granted to the archbishop of Canterbury under certain restrictions. It is under this general transference of papal jurisdiction that *Lambeth degrees* are granted. It is hardly necessary to state, however, that this dispensary power is never exercised in civil cases, and but in a few cases of purely ecclesiastical cognisance, and in those the usage has become the law rather than the exception. The right of the archbishop to grant special licences of marriage, has been expressly recognised by the legislature.

Formerly also the crown claimed a dispensing power, by which it could exempt a person from the ordinary liabilities to the laws of the realm; the limits of which were never exactly defined. It was expressly abolished by the Bill of Rights on the accession of William and Mary.

DISPERSION. Light, as we receive it from the sun or from other original sources, as a star, a fire, a candle, &c., appears to the senses as a simple undecomposable element by the intrumentality of which objects are perceived; and as for the peculiar colours of bodies, we naturally consider them, according to our early impressions, as belonging to the bodies themselves, or inherent in them. We are partly undeceived in this view by the changing colours of birds' feathers, soap-bubbles, &c.; but we are enabled to trace the immediate cause of the colours of bodies, whether permanent or transient, by the analysis of light furnished by the well-known experiments of the glass prism.

The triangular prism used for this purpose is a solid, terminated by two equal and exactly similar triangles, and having besides three plane faces of a rectangular form, contained by the sides of the triangles and by right lines or edges joining corresponding angles of the two triangular bases above-mentioned; and any imaginary right line within it parallel to these edges around which the prism is capable of revolving is called the *axis of the prism*.



In the annexed figure the triangle B A C represents a section of the prism parallel to its basis or perpendicular to its axis: D E we shall suppose to be a ray or exceedingly narrow beam of solar light incident from *vacuum* or air on the prism at E; this ray of white light enters the prism at that point, and having undergone refraction by the dense medium of the glass, no longer proceeds as a simple ray E F, but is *dispersed* or divided into various rays of different colours over the space represented in the figure by *f* E F, and emerging at *f*, F from the prism, undergoes another refraction, such that the portion *fg* of the ray proceeding from *f* is still more refracted than the portion F G from F; let now this dispersed beam *g f* F G be intercepted by a screen or wall P K, from which extraneous light is as much as possible excluded, we shall then find the elongated space G *g* brilliantly painted over with tints passing gradually and insensibly from deep red to an attenuated violet, in the following order, as described by Newton, and since very generally concurred in,—red, orange, yellow, green, blue, indigo, violet. This experiment, which first opens the analysis of light, is easily made by letting a beam of sunlight pass through a small circular hole in a shutter, in a darkened room, on a glass prism such as above described, the refracted and dispersed beam being received on the opposite wall, ceiling, or floor, according to the position of the prism.

When the image of the sun, or a star, candle, &c., is thus formed by admission through a small hole, and the refraction of the prism, the coloured space G *g*, which has the same angular breadth in a direction parallel to the axis of the prism as it would have had if the prism were removed and the light received directly on the screen at the same distance from the place of the prism (the screen being in both cases supposed to be held perpendicularly to the incident light), but which is considerably elongated in the perpendicular direction, is called the *spectrum*; and that angle of the prism B A C the sides containing which B A, A C, have been traversed by the ray D E F G, is called the *refracting* angle of the prism.

Suppose, now, that a small orifice, O, is made in the screen at some point of the spectrum, so that rays of any particular colour, green for example, may be transmitted through it; and let the transmitted portion be again submitted to refraction through another prism, this beam being supposed very small, to ensure its purity or near uniformity of colour. It will not, after refraction, be again decomposed, or undergo any alteration of colour; but if the first prism be turned round its axis, which will cause different colours in succession to fall on O, while the direction of the ray incident on the second prism remains unchanged, being that of a line joining O with the first prism, it will be found that as we pass from the red to the violet the ray will be more and more bent round by the refraction of the second prism. This shows that light incident on the first prism, when once decomposed into homogeneous elements by refraction, is then, at least by refraction, not further decomposable, but each element retains its own colour and its own *refrangibility*, or disposition to be bent by refraction.

This experiment will not perfectly succeed with sun-light as above described, because however small be the hole in the window the incident beam will not be a mere ray, on account of the finite angular diameter of the sun, but a cone of very sensible angle, so that the first spectrum will be *impure*, from the finite size and consequent overlapping of the coloured circles corresponding to the elementary kinds of light. It might be rendered pure, but at great expense of light, by limiting the beam by a screen with a small hole placed at some distance from the first hole. But it is far better, according to the method first described by Newton, to combine the prism (which in this case must be placed at a considerable distance from the hole in the window) with a convex lens, and receive the spectrum on a screen placed at the focus of the lens conjugate to the hole in the window. The lens alone collects into a point the divergent pencil of rays of any one kind; the prism alone bends it round as a whole, but differently for the different kinds, without (at least in the position of minimum deviation) affecting the divergency; and the two combined will give a *pure* and brilliant spectrum, but very narrow. To obtain an equally pure and brilliant spectrum, but of considerable breadth, we have only to replace the hole by a narrow aperture parallel to the axis of the prism. If our object be merely to see a pure spectrum, without placing objects in it, we may replace the lens and the screen by the eye and the retina, that is, merely view, through a prism applied to the eye, a slit transmitting light. In this way very pleasing and instructive experiments may easily be made on the action of absorbing media (such as coloured glasses, &c.) on light. Instead of the naked eye, a telescope may be employed; and in this way accurate measures may be taken, supposing the telescope to be properly mounted, and furnished with cross wires.

We have seen that compound light, the sun's for example, may be decomposed into its homogeneous constituent rays by refraction through a transparent prism. Conversely it may be recompounded into light similar to the original, merely by making the rays thus separated, by another refraction to occupy the same place. This may be effected by placing a prism of exactly similar material and form to that already used, with its refracting angle turned in a direction opposite to that of the former, so that the near faces of both prisms may be parallel; for the rays entering the second prism are in the same condition as if we supposed their direction inverted, that they may repass through the first; and therefore they emerge in a similar compound ray with the original, which may also be easily confirmed by experiment.

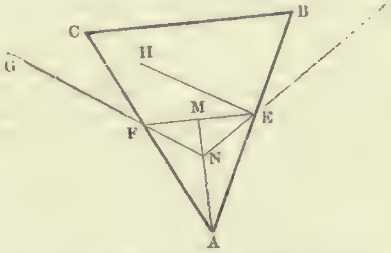
The rays issuing from the second face of the refracting prism, may also be collected by means of a large convex lens, placed at a considerable distance from the prism. If the rays after passing through the lens be received on a screen of white paper, which is first held close to the lens and then moved away, the spectrum will contract in width, until at the focus conjugate to the prism the colours disappear, the original compound white light being reproduced, after which the colours reappear in the reverse order.

The prismatic analysis of light, together with the phenomena relative to the transmission and absorption of light, enabled Newton to conclude that the colours of natural bodies are not inherent qualities of those bodies, but depend on their powers of reflecting, transmitting, or absorbing the rays of some colours more than others from the compound light incident on them; for all bodies placed in homogeneous light of any colour appear themselves to be of that colour, though they are most luminous (making allowance for the different intensity of different parts of the spectrum) when placed in that coloured light which they reflect most copiously. Hence also arise the different colours of coloured liquids or glasses. [ABSORPTION.]

Many of the prismatic colours may be imitated by mixing colours taken, as they lie in the spectrum, of greater and less refrangibility, as orange from red and yellow, &c., but such compound colours are not identical with the homogeneous light of the same colour, being immediately decomposed when viewed through a prism.

If the original prism B A C be turned gradually round its axis, presenting always to the incident light the same refracting angle A, the spectrum G *g* may be made to descend towards K, but after arriving at a certain point where the deviation, that is the inclination of D E produced to F G, is a minimum, it then re-ascends, and it is usual to make the chromatic experiments in this definite position of minimum deviation. This occurs when the position of the prism is such that the angles of incidence and emergence, or their complements D E B, G F C, are equal; for when the moving point G has reached its lowest place, it is for a moment in the condition of a fixed point like the point D, through which we may suppose the incident beam admitted; hence rays proceeding from D, notwithstanding a small variation of incidence arising from the rotation of the prism, reach G, as if it were a fixed point; and since in dioptrics it is of no consequence to the *path* in what direction we suppose the rays to move, it follows that rays proceeding from G, notwithstanding a small alteration of the angle C F G, would arrive at the fixed point or orifice D; and consequently the *data* for the determination of the angles D E B, G F C, in the position of minimum deviation, are precisely the same, and therefore these angles must then be equal.

This being premised, the following easy calculation will give the necessary angle of incidence to produce a minimum deviation.



Since the angles of incidence and emergence are equal, the angles formed by the interior ray E F with both sides of the prism are equal, or the triangle A E F is an isosceles; let 2α be the refracting angle of the prism, then drawing A M perpendicular to E F, we have $\angle$ E A M $=\alpha$, which being the complement of A E M, is necessarily the angle of refraction; if, therefore, μ be the index of refraction for rays of any given colour, the angle of incidence P, corresponding to a minimum deviation, is given by the equation,

$$\text{Sin } P = \mu \sin \alpha \quad . \; . \; . \; . \quad (1)$$

Also the deviation of the ray at either refraction is equal to the excess of P, the angle of incidence, over the angle of refraction, which in this case is equal to α. If then D be the whole deviation, or the angle between the directions of D E and F G, and $i = 2\alpha$, the whole angle of the prism, we get from (1)

$$\text{Sin } \frac{D+i}{2} = \mu \text{ Sin } \frac{i}{2} \quad . \; . \; . \; . \quad (2)$$

The angles i and D, and consequently the value of μ, admit of very exact determination by using a telescope properly mounted, provided we can find in the spectrum an object sufficiently precise to fix on. The transition from one colour into another is far too gradual to allow us to fix on the limit which separates them; but fortunately we have been put in possession of perfectly definite standard objects by the beautiful discovery made by Wollaston and Fraunhofer of the existence of dark spaces, narrow bands transverse to the length of the spectrum, and now generally designated Fraunhofer's lines.

These bands are best observable by forming the spectrum of a luminous line instead of a point, by means of a prism of great purity, and viewing it through a telescope of good magnifying power, though some of them may, when carefully pointed out, be recognised by the unassisted eye, and after one recognition are in future easily found; and for naked eye observations a prism of moderate purity will suffice. They are spaces totally deficient of light, of very unequal width, and exceedingly numerous; it is also to be remarked that these bands, always the same in number and relative position for the same light, are different, or altogether wanting, when the source of light is varied. Thus sunlight, moon-light, planet-light, sky-light, derived from a common source, have the same lines, but several of the fixed stars have dark lines of their own, while artificial lights rarely if ever exhibit dark lines, but frequently show *bright* lines, of which the light of the electric spark is almost wholly made up.

In the formula (2) suppose the angle of the prism i, and consequently the deviation D, to be very small, then

$$D = (\mu - 1)\, i, \quad . \; . \; . \; . \quad (3)$$

a formula which may be readily shown to remain true so long as the angle of incidence is small, even though the angles of incidence and emergence should no longer be equal.

Suppose now that while D, μ relate to rays of mean refrangibility they become D_1, μ_1 and D_2, μ_2 for two definite kinds of rays chosen as nearly as may be at the red and violet extremities of the spectrum. The formula (3) shows that the *difference* of deviation $D_2 - D_1$, or δD, that is the length of the spectrum, is expressed by $(\mu_2 - \mu_1)\, i$ or $\delta\mu . i$. The ratio of the difference of deviation $\delta\mu . i$ to the mean deviation $(\mu - 1)\, i$, or $\frac{\delta\mu}{\mu - 1}$, depends (for given selected rays) only on the nature of the substance of which the prism is made, and is called the *dispersive power* of the substance.

Newton supposed that all substances disperse light in the same proportion as they refract it, and concluded that in refracting telescopes it was impossible to get rid of the defects arising from the chromatic dispersion of the object glass. Mr. Hall was the first to point out Newton's mistake, and to apply the fact of the difference of dispersive power of substances to the construction of an achromatic telescope (Herschel's 'Light,' art. 425); but the discovery fell into oblivion, and it was not until after the fact had been rediscovered by Dollond, and reapplied to the same object, that the achromatic telescope came into general use. The mode in which the compensation is effected by the use of two lenses may be readily understood from the following considerations.

Imagine a single ray to be transmitted through a convex lens in a direction nearly parallel to its axis, but at a good distance from its centre. If tangent planes be drawn at the two points where the ray cuts the surfaces, the refraction of this single ray will be the same as if the lens were replaced by a slender wedge or prism of the same material bounded by these tangent planes. Consequently the ray will be not only deflected as a whole, but "dispersed." If now we consider all the rays emanating from a distant point in the axis of the lens we readily see that the violet rays will be brought to a point or focus in the axis of the lens sooner than the green, the green than the red, &c. At no one distance will all the rays be brought to a focus together, and consequently the image will be confused.

Suppose now we have two slender prisms, composed of different materials, in contact with one another or nearly so, with their angles i, i' turned in contrary directions; and let a ray of white light be incident nearly perpendicularly upon the system. The deviations produced by the two prisms being $(\mu - 1)\, i$ and $(\mu' - 1)\, i'$, the whole deviation will be

$$(\mu - 1)\, i - (\mu' - 1)\, i', \quad . \; . \; . \; . \quad (3)$$

while the *difference* of deviation of the red and violet rays will be

$$\delta\mu \, . \, i - \delta\mu' \, . \, i' \quad . \; . \; . \; . \quad (4)$$

Unless therefore $\delta\mu : \mu - 1 :: \delta\mu' : \mu' - 1$, that is unless the dispersive powers of the two substances are the same, the difference of deviation may be destroyed without at the same time destroying the common deviation of the two kinds of rays. The outstanding deviation will be in the direction of that produced by the prism of smaller dispersive power.

Suppose now that a compound lens is formed consisting of a convex and concave of substances differing in dispersive power; and imagine the course of a ray incident towards the edge in a direction nearly parallel to the axis. By drawing tangent planes as before, the lenses may, as regards the course of this single ray, be replaced by a pair of prisms turned in contrary directions. The small chromatic variations of the points of incidence, and consequently of the angles of the prisms, arising from the dispersion of the ray during its passage through the lenses, may be altogether neglected. Now the deviations being on the one hand as $(\mu - 1) i$ to $(\mu' - 1)\, i'$, and on the other inversely as the focal lengths F, F' for parallel rays, we have $(\mu - 1)\, F . i = (\mu' - 1)\, F' . i$, and substituting in (4) equated to zero we find

$$\frac{\delta\mu}{\mu - 1} \, \frac{1}{F} = \frac{\delta\mu'}{\mu' - 1} \, \frac{1}{F'},$$

or in order that the dispersion may be corrected, the focal lengths must be as the dispersive powers.

The dispersive power of substance is most accurately determined by forming the substance into a prism of considerable angle (supposing it sufficiently homogeneous), and determining, as before explained, the refractive indices for two properly selected and perfectly definite points of the spectrum, such as two fixed lines. The ratio of the dispersive powers of two substances, which is all that is required for the construction of an achromatic object-glass, may, however, be determined by different methods of compensation. One of the simplest, at least in theory, which has been much employed by Dollond and practical opticians up to the present day, consists in forming two prisms of the substances with small angles, and altering by trial the angle of one of the prisms until an object seen through both appears as free as possible from fringes of colour, when the dispersive powers are inversely as the deviations produced by the two prisms respectively.

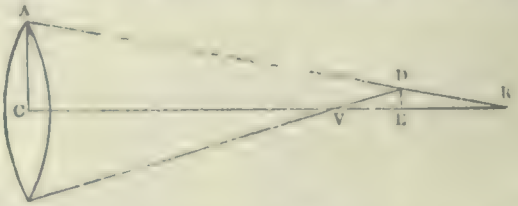
When different substances are formed into slender prisms through which light passes nearly perpendicularly, not only does the separation of the extreme rays bear to the mean deviation a different ratio in the different substances, but the ratio of the angular extent of one portion of the spectrum to that of another portion changes from substance to substance. Thus if three definite points, (such as three fixed lines,) be taken in the red, the green, and the violet, the ratio of the separation of the violet from the green to that of the green from the red will be greater in flint glass than in crown. This want of proportionality is termed the *irrationality of dispersion*, and the outstanding spectrum formed when two prisms as nearly as possible compensate each other, which is coloured green on one side and purple (from a mixture of red and blue) on the other, is called a *secondary spectrum*. This irrationality prevents the compensation in the case of a double object glass from being perfect, and constitutes one of the chief obstacles to the perfection of large refracting telescopes.

The rainbow is a beautiful natural exhibition of the dispersion of light into spectral colours. [RAINBOW.]

Two simple propositions relative to the effect of chromatic dispersion in a single lens are here subjoined.

To find the longitudinal chromatic aberration of a lens, or the interval on the axis between the foci of extreme red and violet rays.

Let the red rays converge to the point R, and the violet to the point V in the axis.



Let f, F be respectively the focal distances for the given system of rays, and a parallel system; then the fundamental equations for lenses (neglecting their thickness), give $\frac{1}{f} - \frac{1}{F} =$ constant, since the rays of all colours in the compound incident beam have a common origin; now differentiate relative to μ, the variable index of refraction: hence,

$$\frac{df}{d\mu} = \frac{f^2}{F^2} \cdot \frac{dF}{d\mu};$$

but since F is proportional to $\mu - 1$, therefore $\frac{1}{F} \cdot \frac{dF}{d\mu} = \frac{1}{\mu - 1}$; and if $\delta\mu$ denote the total variation of μ from extreme red to violet, and δf the corresponding variation of f, or longitudinal aberration, and finally h, the dispersive power of the medium, we have

$$\delta f = \frac{df}{d\mu} \cdot \delta\mu = \frac{f^2}{F} \cdot \frac{\delta\mu}{\mu - 1} = h \cdot \frac{f^2}{F}.$$

To find, in the same case, the radius of the circle of least chromatic dispersion.

By referring to the same figure, we may observe that the foci R, V are respectively the vertices of red and violet conical surfaces, having the lens as a common base. Let these surfaces intersect in a circle, of which the radius is D E; then it is plain that all the intermediate coloured rays pass through this circle. It is therefore that of least dispersion:

The preceding figure representing a plane section of the whole system taken through the axis, it is obvious that, from the smallness of R V relative to C R, the angles C V B, C R A are sensibly equal, or the triangle V R D is exceedingly nearly isosceles, and therefore D E bisects V B, or $ER = \frac{\delta f}{2}$ and $DE = ER \cdot \frac{CA}{CR} = \frac{h}{2} \cdot \frac{f}{F} \cdot CA$, and for parallel incident rays $DE = \frac{h}{2} \cdot CA$.

DISPOSITION, in the law of Scotland, is the name given to an instrument, or as it would be termed in England, deed poll, by which a party solemnly makes over to another real property. It may be used as a title to moveables alone, but it is in the law of real property that it is of most frequent use and of highest importance, the conveyance of moveables being usually by assignation or assignment. When a new feu or fief is created, it is by charter or contract of feu, containing a disposition in itself, or disposition in feu; but when a feu, fief, or estate is transferred from one holder to another it is by Disposition, in which all the conditions on which the property is to change hands are set forth. Being given to the disponee, it is in his hands a personal obligation by the disponer to give him a full title, and contains the warrants for getting the title made real by registration, and by obtaining the superior's sanction to the new investiture. As heritable property cannot be bequeathed by testament in Scotland

[WILL], the usual form of family settlements in which such property is disposed of is the disposition.

DISSECTION. The art of separating the parts of organised bodies in such a manner as to display their structure. It is an art equally applicable to both divisions of the organic kingdom, and indispensable alike to the discovery of the structure of plants and animals. The grounds on which, for the well-being of the community, every facility should be afforded to the cultivation of this art, as far as regards human dissection, have been already stated. [ANATOMY ACT.] It is satisfactory to observe that the prejudices which formerly obstructed this practice are rapidly disappearing, and that even the most uneducated are beginning to appreciate its great importance and its signal utility.

DISSEISIN. [SEISIN.]

DISSENTERS, the general name for the various Protestant religious sects in this country that disagree in doctrine, discipline, or mode of worship with the Established Church. The Jews and Roman Catholics are not commonly called dissenters. The origin of Protestant dissent from the Church of England is usually traced back to the year 1548, in the reign of Edward VI., when a controversy arose among the adherents of the new Reformation in consequence of the excellent Hooper (afterwards the martyr) scrupling to be consecrated as bishop of Gloucester in the customary canonical habit, which he deemed objectionable as a relic of Romanism. Hooper eventually received consecration without being attired in canonicals. At this time the two parties received the names of Conformists and Nonconformists; very soon after that of Puritans came into use as the general appellation of the dissenters, and it continued to be that by which they were commonly distinguished down to the close of the civil wars in the next century. The toleration of the dissenters, even in the most limited extent, dates only from the Revolution. During the century and a half that elapsed between the Reformation and that event, with the exception only of the short period of the Commonwealth, during which first the Presbyterians and afterwards the Independents had the ascendancy, they continued to be persecuted by a succession of restrictive and penal laws of almost constantly increasing severity. It was not till 1828 that the dissenters were raised from being a merely tolerated body to a free participation in the rights of their fellow-subjects, by the abolition of the Test and Corporation Acts. If the relaxation of the marriage law, that has since taken place, shall be followed by the abolition of Church rates, the dissenters will be placed as nearly on an equality in all respects with the adherents of the Established Church as it is possible that they should be, without the Established Church itself being abolished. In the early times of dissent the great classes of dissenters were the Presbyterians, the Independents, the Baptists, and the Quakers. The most numerous now are the Methodists, or followers of Wesley and Whitfield, some only of whom are avowedly dissenters. The Methodists are subdivided into Wesleyan Methodists, Primitive Methodists, United Free Church, &c. The minor sects of dissenters now make a long list; but many of them may be considered as only subdivisions of or included in the four leading denominations. Until the formation of the Free Church, the most numerous classes of dissenters in Scotland were those which originated in a separation from the Established Church in 1736. [ERSKINE, EBENEZER, in BIOG. DIV.] They were called generally Seceders, and were divided into Burghers, Anti Burghers, Original Burghers, and Original Seceders. The greater number of the Burghers and Anti-Burghers united in 1820, under the designation of the United Associate Synod of the Secession Church; in 1847 this body united with the Relief Church (which originated in a separation from the Establishment in 1752), the aggregate body taking the name of the United Presbyterian Church. The Free Church of Scotland, which separated from the Establishment in 1843, forms now the most numerous body of dissenters in Scotland, although in some respects the members of the Free Church disclaim the designation of dissenters. These bodies are all Presbyterians, and differ chiefly on the theory of the relations of the Church to the State. The only considerable body of Scottish dissenters of older standing, with the exception of the Episcopalians, is that of the Cameronians, or Reformed Presbyterian Synod, who are the representatives of the Covenanters of the 17th century. The Congregationalists, or Independents, form a considerable body in Scotland; the Baptists, of whom there are several sections, are fewer in number. In Ireland, exclusive of the Roman Catholics, the principal dissenters are the Presbyterians, who are mostly confined to the province of Ulster. In the Census of 1851 an attempt was made to ascertain the number of each sect, by taking the number who attended divine service on a certain Sunday, but the result was confessedly imperfect, though it may afford a rough approximation. [CENSUS OF THE UNITED KINGDOM, vol. ii., col. 723.]

DISSONANCE, in music, a term synonymous with discord. [DISCORD.]

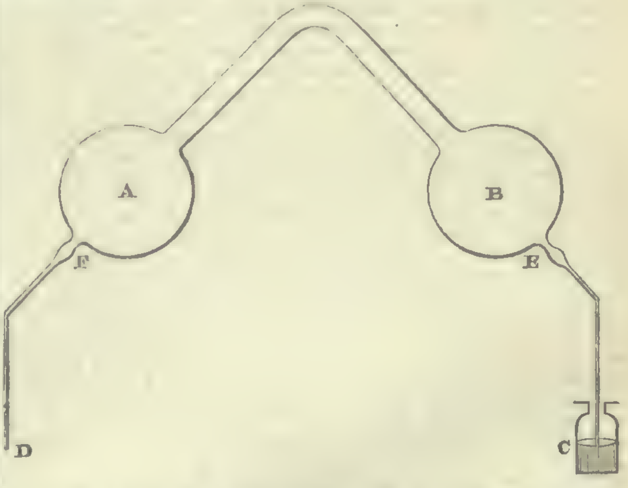
DISTANCE. The only remark which we need make upon this common word is that it is very frequently applied to *angular* distance, meaning the angle of separation which the directions of two bodies include. In the apparent sphere of the heavens, distance always means angular distance. The term *apparent* distance is frequently applied in the same case.

DISTEMPER, an inferior kind of colouring, in which size is the principal vehicle employed for mixing with the colour. It is used for both internal and external walls, but principally for the former, instead of oil colour, being a cheap substitute.

It is composed of whitening mixed with size of a coarse quality, in the proportions of twelve pounds of whitening to one of size. The size is boiled and reduced to a proper working consistency by the addition of water, after which the colour is added to form the necessary tint. Coarser colours are used for distemper than are employed in oil-painting and colouring. Scene-painting is executed in distemper, and paper-stainers employ distemper colour in printing and staining papers for walls. The colours used in these cases are, however, of a better quality, and the size employed is made from the hide of the buffalo, or parchment cuttings. The proportions of size and whitening in paper-staining depend on the strength of the size. In five quarts of distemper, if the size be strong, one-fourth part will be sufficient; if weak, about one-half. In mixing the size and whitening much depends on the judgment of the workman. The distemper is used in a chilled state. Five quarts will stain about eighty-four yards of paper.

The method of painting of the early Italian painters before the employment of oil as a vehicle, is known as *tempera*, from which term our word distemper as applied to painting is no doubt derived.

DISTILLATION. The process of separating, by the aid of heat, a volatile from a fixed or less volatile constituent. Sometimes the volatile matter so separated condenses as a solid, and then the process is termed *sublimation*. [SUBLIMATION.] When the product obtained is the result of a change induced by heat upon the original substance, the operation is named *destructive* or *dry distillation*. The ordinary process of gas-manufacture, wherein certain liquid products are condensed, is a process of dry distillation. Distillation in the unqualified sense, however, signifies the volatilisation of a liquid by heat and its subsequent condensation in a separate vessel by cold. It is employed to separate a volatile liquid from less volatile solid or liquid matters. It is thus largely employed in the arts (see following article). In chemistry the operation is generally performed in an apparatus figured under CONDENSER. The material to be operated upon is placed in a *flask* or *retort* connected with the higher extremity of a condenser, which conducts the liquified product to a vessel called the *receiver*. In order to attain perfect purity from the less volatile matter, the process of distillation must in many cases be repeated, and it is then termed *rectification*. Some liquids, on being boiled in glass vessels, produce sudden bursts of vapour often causing the fracture of the vessel; this inconvenience may generally be remedied by placing platinum wire, or angular particles like quartz-sand, at the bottom of the vessel. Thus concentrated sulphuric acid can only be safely distilled in glass vessels, by first converting it into a magma with quartz sand. It is sometimes desirable to protect liquids from the air, or to lower their boiling points [BOILING OF LIQUIDS]; in either case distillation in vacuo is resorted to. When small quantities only of liquid are thus to be operated upon, the following is a very convenient form of apparatus:—



A B are two glass bulbs blown near the ends of a tube about one foot long, the extremities of the tube beyond the bulbs being drawn out as shown in the figure. The capillary tube attached to B is now immersed in the liquid to be distilled contained in the bottle C, and suction being applied to D, the necessary amount of fluid is raised into B, which is then so inclined as to prevent its return. The neck E of the capillary tube is now to be sealed off by the mouth-blowpipe, and the extremity D connected with an air-pump, by means of a caoutchouc joint. A vacuum being thus made in the bulbs, the tube D is fused off at F, and the distillation may now be commenced. The empty bulb A being immersed in cold water, the necessary heat is applied to B until a sufficient amount of the liquid has distilled over. The tube connecting the two bulbs must now be cut across with a triangular file, and the products removed from the bulbs.

DISTILLERY. Having, in the article DISTILLATION, explained the chemical principles on which all distilling processes necessarily rest, we shall now treat of these processes in their practical connection with manufactures, especially the distilling of ardent spirits in those great establishments known as distilleries.

The Arabians seem to have practised, in the remotest ages, the art of extracting the aromatic essences of plants and their flowers, in the form of distilled waters, to supply the luxuries of oriental baths. They are also supposed to have been the first to extract from wine a colourless intoxicating liquor by distillation. From certain passages in Pliny and Galen there can be no doubt that the Greeks and Romans were well acquainted with the distillation of aromatic waters. Indeed Nicander, a Greek poet and physician who lived 140 years before the Christian era, employs the terms ἄμβιξ *ambix* and distillation in describing the preparation of rose-water. From ambix, which signifies a pot, the Arabic name alambic or alembic is derived. The words *pot* and *poteen* are used in the same way by the modern Irish to designate a still and its spirituous product. It is obvious that distillation must have been a familiar process to the countrymen of Avicenna, since, in his treatise of catarrh, he compares the human body to an alembic; he regards the belly as the cucurbit or body, and the head as its capital, through which the humours distil, passing off by the nostrils as its beak.

Arnoldus de Villa Nova, a chemical physician of the 13th century, is the first author who speaks explicitly of an intoxicating spirit obtained by the distillation of wine; and he describes it as a recent discovery. He considers it to be the universal *panacea* so long sought after in vain. His disciple Raymond Lully, of Majorca, declares this admirable essence of wine to be an emanation of the Divinity, an element newly revealed to man, but hidden from antiquity because the human race were then too young to need this beverage, destined to revive the energies of modern decrepitude. He further imagined that the discovery of this *aqua vitæ*, as it was called, indicated the approaching consummation of all things—the end of the world. In his 'Chemical Theatre,' written towards the close of the 13th century, Lully describes the distillation of ardent spirits thus: "Limpid and well-flavoured red or white wine is to be digested during twenty days in a close vessel by the heat of fermenting horse-dung, and to be then distilled in a sand-bath with a very gentle fire. The true water of life will come over in precious drops, which being rectified by three or four successive distillations, will afford the wonderful *quintessence* of wine. . . . . To prove its purity," adds he, "if a rag be dipped in it, and kindled, it will not become moist, but consume away."

The only substances employed in this country in the manufacture of ardent spirits upon the great scale are different kinds of corn, such as barley, rye, wheat, oats, buckwheat, and maize. Peas and beans have been occasionally used in small quantity. The principles in these grains from which the spirits are indirectly produced are starch and a little sweet mucilage, which, by a peculiar process called *mashing*, are converted into a species of sugar. It is the sugar so formed which is the immediate generator of alcohol, by the process of fermentation. In mashing one or more kinds of corn, a greater or smaller proportion of malt is always mixed with the raw grain; and sometimes malt alone is used, as in the production of malt whiskey. The process of malting is that incipient growth called germination, in which, by the disengagement of a portion of the carbon of the starch, in the form of carbonic acid, the ultimate vegetable elements become combined in such a proportion as to constitute a species of sugar. Malting is the most effectual method of converting starch into sugar; although chemists are acquainted with other and very singular modes of effecting this transformation. By mashing, a larger or smaller proportion of the *fecula* of the corn is thereby converted into sugar, and thus brought into a state fit for producing alcohol by fermentation.

The manufacture of ardent spirit, whether known as whiskey or by any other name, consists in three distinct operations: first, mashing; second, fermentation; third, distillation.

1. *Mashing.*—Either malt alone, or malt mixed with other grain, and coarsely ground, is put into the mash-tun, along with a proper proportion of hot water; and the mixture is subjected to agitation by a mechanical revolving apparatus, similar to that employed in the breweries for the manufacture of beer. When malt alone is used, the water first run into the mash-tun among the meal has usually a temperature of 160° or 165° Fahrenheit; but when a considerable proportion of raw grain is mixed with the malt, the water is let on at a lower temperature, as from 145° to 155°. The following quantities have been found to afford a good product of whiskey in a well-conducted Scotch distillery:—

252 bushels of malt, at 40 pounds per bushel.
948 „ barley, 53¾ „ „
150 „ oats, 47½ „ „
150 „ rye, 53¾ „ „
——
1500

From each bushel of the above mixed meal 2⅓ gallons of proof whiskey (specific gravity 0·921) may be obtained, or 18⅔ gallons per quarter. A few distillers are skilful enough to extract 20 gallons per quarter from such a mixture. Ten imperial gallons may be considered a fair proportion of water to be introduced into the mash tun for every bushel of meal at the first infusion. After two or three hours' agitation, the whole is left to repose for an hour and a half, and then the worts are drawn off to about one third the volume of water employed, the rest being entangled in a pasty state among the farina. About two-thirds of the first quantity of water is now let into the tun, but at a temperature somewhat higher; and the agitation is renewed for nearly half an hour. A second period of infusion or repose ensues, after which these second worts are drawn off. Both infusions must be cooled as quickly as possible down to the temperature of 80° or 70° Fahr., otherwise they are apt to run into the acetous fermentation by the rapid absorption of oxygen. This refrigeration is usually effected by exposing the wort for some time in large shallow coolers, placed near the top of the building, where it may be freely exposed to the aërial currents. But it is sometimes cooled by being passed through serpentine tubes surrounded with cold water, or by the agency of ventilators blowing over its surface in extensive cisterns only three or four inches deep.

After the second wort is drawn off, a third quantity of water, fully as great as the first, but nearly boiling hot, is run into the mash-tun, and well incorporated with the magma by agitation; after repose, this third wort is also drawn off, cooled, and either directly mixed with the preceding worts, or after it has been concentrated by boiling down; in most cases, however, it is reserved, and used instead of water for the first infusion of a fresh quantity of meal. The mashing and fermentation are jointly called *brewing*, and the period in which they are carried on is by law kept quite distinct from the *distilling* period, the one occupying usually one week, and the other the next in rotation. About 150 gallons of wort or wash are obtained from each quarter of corn employed.

The first of the above worts will have generally the density of 1·078 when the grain is good and the mashing is well managed, and the second a density of 1·054, so that the mixture will have a specific gravity somewhat above 1·060, and will contain about 60 pounds of extract per barrel. Now, by the excise rules, 100 gallons of such wort ought to yield one gallon of proof spirit for every five degrees of attenuation which its specific gravity undergoes in the fermenting tun, so that if it falls from 1·060 to 1·000, 12 gallons of proof spirit are supposed to be generated, and must be accounted for by the distiller. After an alteration in the excise laws some years ago, the distillers were allowed to ferment worts of less density than they previously could, and have been able to effect a more productive fermentation. They have been also enabled thereby to reduce the proportion of malt in the mixed meal. Formerly they were accustomed to use three parts of malt to four parts of barley, or two to three, but they soon diminished the malt to one-fifth, and latterly to one-eighth, or one-tenth, of the whole grain. One principal use of malt, besides its furnishing the saccharine ferment called diastase, is to keep the mash magma porous, and facilitate the drainage of the worts.

2. *Fermentation.*—This is undoubtedly the most intricate, as it is the most important process in distillation. Experiments have proved that the quantity of saccharine matter converted into alcohol is dependent upon the proportion of ferment or yeast introduced into the worts; if too little be used a portion of the sugar will remain undecomposed; and if too much, the spirits will contract a disagreeable taste. In general, the worts are let down at the specific gravity of 1·050 or 1·060, and at a temperature varying from 60° to 70° Fahr. For every 100 gallons one gallon of good porter yeast is immediately poured in and thoroughly incorporated by agitation with a stirrer. When by attenuation the density is diminished to 1·035, one half gallon more is added, and another half gallon at the density of 1·025, after which the worts usually receive no further addition of yeast. The temperature of the fermenting mass rises soon after the introduction of the yeast 8 or 10 degrees, and sometimes more; so that it reaches in some cases 85° or 90° Fahr. From the appearance of the froth or scum the experienced distiller can form a tolerably correct judgment as to the progress and quality of the fermentation. The greatest elevation usually takes place within thirty-six hours after the commencement of the process. The object of the manufacturer of spirits is to push the attenuation as far as possible; this so far differs from that of the beer-brewer, who wishes always to preserve a portion of the saccharine matter undecomposed to give flavour and body to his beverage. The first appearance of fermentation shows itself by a ring of froth round the edge of the vat usually within an hour after the addition of the yeast; and in the course of five hours the extrication of the carbonic acid from the particles throughout the whole body of the liquor causes frothy bubbles to cover its entire surface. The temperature meanwhile rises from 10 to 15 degrees, according to circumstances. The greater the mass of liquid, the lower the temperature at which it was let down into the tun, and the colder the surrounding atmosphere, the more slowly will the phenomena of fermentation be developed under a like proportion of yeast and density of the worts. In general large vats afford a better result than small ones, on account of the equality of the process. It is reckoned good work when the specific gravity comes down to 1·000, or that of water; and superior work when it falls 4 or 5 below it, or to 0·995.

After thirty-six hours upon the moderate scale the yeasty froth begins to subside; and when the attenuation gets more advanced, the greater part of it falls to the bottom on account of its density relatively to the subjacent fluid. In from forty-eight to sixty hours the liquor begins to grow clear, and becomes comparatively tranquil. It has been deemed advantageous towards the perfection of the fermentation to rouse up the wash occasionally with a proper stirrer, and in some cases to increase its temperature a few degrees by the transmission of steam through a serpentine pipe coiled round the sides of the vat. Some have imagined that a considerable portion of spirit is carried off by the great volume of carbonic acid evolved, and have proposed to save it by covering the vats air-tight, and conducting the gas through a pipe in the lids into a vessel containing water. The economy of this apparatus is not worth the expense and trouble which it occasions. The distillers content themselves with enclosing their vats after the first violence of the action under tolerably tight covers. It is found that the acetous fermentation is always proceeding simultaneously with the vinous fermentation: for judging by the usual tests there is always a slight degree of acidity in fermenting wash; that vinegar is in fact forming along with alcohol, or that while the attenuation is increasing, acetic acid is being formed. This important fact serves to show how very fallacious a test the attenuation or diminution of density is of the amount of alcohol generated and existing in a fermented wash. The acetic acid along with the undecomposed mucilaginous starch may, in fact, so far counteract the attenuating effect of the spirits as to produce a specific gravity which shall indicate 10 or 15 per cent. less spirit than is actually present in the wash.

It is computed that every 5 degrees of attenuation, as it is called, that is every diminution of the number 5 upon the specific gravity in the third place of decimals, ought to produce 1 per cent. of proof spirit, or 1 gallon out of 100; so that if the wort be set at 1·055, and come down to 1·000, 11 gallons of proof spirits are chargeable upon each 100 of such wash. In the fermentation of sugar worts, 1 gallon of proof spirits was calculated for every four degrees of attenuation; but distillation from sugar or molasses-wash is now illegal. With corn-wash there is never more than four-fifths of the saccharine matter decomposed into alcohol and carbonic acid, in the best-managed fermentation, and frequently indeed much less. In fact, each pound of real sugar may be resolved by a successful process into half a pound of alcohol, or into about one pound of proof spirit; and hence as a solution of sugar at the density of 1·060 contains 15 per cent. by weight, or 16 per cent. by measure, which is nearly 1·7 pounds per gallon, it should yield nearly 170 pounds from 100 gallons, or 180 pounds measure equal to 18 gallons of proof spirit; whereas 100 gallons of corn-wash, fermented at the above density, are computed by the excise law to yield only 12 gallons, and seldom produce more than 13 and a small fraction.

In the huge fermenting vats used by the corn distillers of this country, the fermentation goes on far more slowly than when conducted upon the moderate scale referred to in the account of this process given above. About 1 gallon of yeast is added at first for every 100 gallons of wort, and a half gallon additional upon each of the succeeding four days, making in the whole 3 per cent,; when less can be made to suffice, the spirits will be better flavoured. The fermentation goes on during from six to twelve days, according to the modifying influence of the circumstances above enumerated. After the fifth or sixth day, the tuns are covered in, so as to obstruct, in a certain degree, the discharge of the carbonic acid: since it is supposed that this gas in excess favours fermentation. The temperature is usually greatest on the fourth or fifth day, when it sometimes rises to 85° Fahr., from the starting pitch of 60° or 56°. Whenever the attenuation has reached the lowest point by the hydrometer, the wash ought to be distilled, since immediately afterwards the alcohol begins to be converted into acetic acid. This acidification may be partially repressed by the exclusion of atmospheric oxygen.

III. *Distillation.*—There are few kinds of chemical apparatus which have undergone so many metamorphoses as the still and condenser. In its simplest form it has been already represented and described. [ALEMBIC.] It may be considered to have reached its highest point of perfection, as to power and rapidity of work in Scotland, at the time when the distillers paid a stipulated sum per annum to the revenue for the privilege of using a still of a certain size, and when therefore they derived a profit proportionable to the quantity of spirits they could run off in a given time. Since the year 1815, the whiskey duties have been levied on the quantity distilled, independent of the capacity of the still. This change has introduced a modification in the distilling apparatus, with the view of combining purity of product with economy of time. The body of the still is still comparatively flat, so as to expose a large surface to the fire; but the tapering upper part, corresponding to the capital of an alembic, is made very long, rising sometimes 15 or 20 feet before it terminates in the worm pipe or refrigeratory for condensation.

Great distilleries are usually mounted with two stills, a larger and a smaller. The former is the *wash* still, and serves to distil from the fermented worts a weak crude spirit called *low wines;* the latter is the low-wine still, and rectifies by a second process the product of the first distillation. The annexed cut represents a copper wash-still, having a capacity of about 20,000 gallons. In these successive distillations a quantity of fetid oil, derived from the corn, comes over along with the first and last portions received, and constitutes by its combination what is styled, in the language of the distilleries, the strong and weak *faints.* These milky faints are carefully separated from the limpid spirit by turning them as they begin to flow from the worm-end into distinct channels, which lead to separate *receivers.* From these receivers the various qualities of spirit, low wines, and faints, are, for the purpose of redistillation, pumped up into charging backs, from which they are run in gauged quantities into the low-wine and spirit stills.

Wash Still.

One of the greatest improvements in modern distillation is the accomplishment of this essential analysis of the impure spirit at one operation. Chemistry had been long familiar with the pneumatic apparatus of Woulfe, without thinking of its adaptation to distillery apparatus; when Edouard Adam, an illiterate operative, after attending by accident a chemical lecture at Montpellier, where he saw that apparatus, immediately employed it for obtaining fine brandy, of any desired strength, at one and the same heat. He obtained a patent for this invention in July, 1801, and soon afterwards was enabled by his success to set up in that city a magnificent distillery, which attracted the admiration of all the practical chemists of the day. In November, 1805, he obtained a certificate of improvements whereby he could extract from wine at one process the whole of its alcohol. Adam was so overjoyed after making his first experiments, that, like another Archimedes, he ran about the streets telling everybody of the surprising results of his new invention. About the same time, Solimani, professor of chemistry at Montpellier, and Isaac Berard, distiller in the department of Gard, having contrived two distinct systems of apparatus, each most ingenious, and obtaining results little inferior to those of Adam, became in consequence formidable rivals of his fame and fortune.

The late Dr. Ure devised a form of distilling apparatus which to him appeared to combine the delicacy of the French with the solidity of the English forms. The lower the temperature of the spirituous vapour which enters into the refrigerator, the stronger and finer will the condensed spirit be; because the noxious oils are less volatile than alcohol, and come over chiefly with the aqueous vapour. A perfect still should therefore, he believed, consist of three parts: first, the cucurbit or boiler; second, the rectifier, for intercepting the greater part of the watery particles, and the whole of the corn oil; and third, the refrigerator. Three principal objects are obtained by this arrangement: first, the extraction from fermented wort or wine, at one operation, of a spirit of any desired cleanness and strength; second, a great economy of time, labour, and fuel; third, freedom from all danger of blowing up or boiling over by mismanaged firing. When a mixture of the alcohol, water, and essential oil, in the state of vapour, is passed upwards through a series of winding passages, maintained at a regulated degree of heat, from 170° to 180°, the alcohol alone, in notable proportion, retains the elastic form, and proceeds onward into the refrigeratory tube, in which these passages terminate; while the water and the oil are, in a great measure, condensed and retained in the passages, so as to drop back into the body of the still, and be discharged with the effete residuum.

The system of channels shown in *fig.* 2 is so contrived as to bring the compound vapours which rise from the alembic A into intimate and extensive contact with metallic surfaces, immersed in a water-bath, and maintained at any desired temperature by a self-regulating *thermostat* or heat-governor. The neck of the alembic tapers upwards as shown at B, *fig.* 1; and at C, *fig.* 2, it enters the bottom or ingress vestibule of the rectifier C F. F is its top or egress vestibule, which communicates with the under one by parallel cases, or rectangular channels, D, D, D, whose width is small compared with their length and height. These cases are open at top and bottom, where they are soldered or riveted into a general frame within the cavity, inclosed by the two covers F, G, which are secured round their edges E, E, E, with bolts and packing. Each case is occupied with a numerous series of shelves or trays, placed at small distances over each other, in a horizontal or slightly inclined position, of which a side view is given in *fig.* 3, and cross sections at D, D, D, *fig.* 2. Each shelf is turned up a little at the two edges and the one end, but sloped down at the other end, so that the liquor admitted at the top may be made to flow backwards and forwards in its descent through the system of shelves, as indicated by the spouts in *fig.* 3. The shelves of each case are framed together by two or more vertical metallic rods, which pass down through them, and are fixed to each shelf. On removing the cover, the sets of shelves may be readily lifted out of the cases to be cleaned; and are hence called *movable*. The intervals I, I, I, *fig.* 2, between the two cases, are left free for the circulation of the water contained in the bath-vessel G, G; these intervals being considerably narrower than the cases. *Fig.* 4 represents in plan the surface of the rectifying cistern, shown by two different sections in *figs.* 2 and 3: H, K, *figs.* 2 and 4, is the thermostat or heat-governor, shaped somewhat like a pair of tongs. *Fig.* 5 is the refrigeratory, consisting of a double tube, placed in a zigzag direction, but in one plane, and supported by the two upright beams. The alcoholic vapour enters at the orifice K, and descends along the inner tube marked by dotted lines till it becomes condensed by the counter-current of water continually ascending in the annular space between that block-tin or copper tube, and the outer cast-iron pipe G. The water of condensation enters into that annular space at the point O, being supplied by the pipe D, and the nose of the stop-cock L. The funnel into which the cold water is poured must be somewhat higher than the point K, from which that water is discharged, after having been heated to the same temperature as that of the alcoholic vapour last exposed to its influence.

Fig. 1.

The still apparatus above described is worked as follows: Into the alembic put as much fermented liquor as will protect its bottom from being injured by the fire, when it is not plunged in a bath of muriate of lime, but exposed directly to the fuel. As soon as the ebullition in the alembic has raised the temperature of the water-bath G G to the desired rectifying pitch, whether 170° or 180°, the thermostatic instrument is to be adjusted by its screw-nut, and then the communication with the charging back or cistern is to be opened by moving the index of the stop-cock O over a proper portion of its quadrantal arch. The wash will now descend in a regulated stream through the pipe O F, thence spread into the horizontal tube P P, and issue from the orifices of distribution into the respective flat trays or spouts. The manner of its progress is shown for one set of trays in *fig.* 3. The direction of the stream on each shelf is evidently the reverse of that in the shelf above and below it; the turned-up end of one shelf corresponding with the discharge slope of its neighbour. By diffusing the cool wash or wine in a thin film over such an ample range of surfaces, the constant tendency of the bath to exceed the proper limit of temperature is counteracted to the utmost without waste of time or fuel; for the wash itself *in transitu* becomes boiling hot, and experiences a powerful steam distillation. Thus also a very moderate influx of water through the thermostat stop-cock suffices to temper the bath; such an extensive vaporization of the wash producing a far more refrigerant influence than its simple heating to the boiling point. It deserves peculiar remark, that the greatest distillation with the least fuel is here effected without any pressure in the alembic; for the passages are all pervious to the vapour; whereas, in almost every wash-still heretofore contrived for similar purposes, the spirituous vapours must force their way through successive layers of liquid, the total pressure from which causes undue elevation of temperature, obstruction to the process, and forcing of the junctures. Whatever supplementary refrigeration of the vapours in their passage through the bath may be deemed proper will be administered by the heat-governor. The bath regulated by the thermostat may however be used for obtaining fine spirits at one operation, without transmitting the wash or low wines down through its interior passages; in which case it becomes a simple rectifier. The empyreumatic taint which spirits are apt to contract from the action of the naked fire on the vegetable gluten in contact with the bottom of the still, is somewhat counteracted by the rotation of chains in the large wash-stills; but it may be entirely prevented by placing the still in a bath of strong solution of muriate of lime R R, *fig.* 1, regulated by a thermometer or, still better, a thermostat. Thus a safe and effectual temperature of from 270° to 290° Fahr. may readily be obtained.

The principle of continuous distillation, just mentioned as having been adopted by Adam about sixty years ago, has been very extensively adopted by French distillers, in relation both to brandy from wine, and to liqueurs of various kinds. Bérard, Blumenthal, Derosne, Laugier, and others, have introduced successive improvements, which have rendered the French stills beautiful pieces of apparatus. In 1852, M. Boutigny, of Evreux, introduced a system of distilling in which two principles were especially held in view. The one was, so to condense the vapour almost at the instant of production, as to insure the conversion of all the alcohol into liquid; and the other was, so to manage the apparatus as to prevent anything from boiling up and over with the alcohol, which might contaminate it. A sheet of wire-gauze, in one or more layers, is placed so as to intercept all substances; while alcoholic vapour is allowed to pass. The vessels are so arranged, that the product distilled from the first apparatus shall serve to feed the second; the second a third; and so on; the last leading into a refrigerator. The boiling arrangements provide for a large heating surface, and a rapid evaporation.

Efficient as may be the French system, it has been found, however, that the small pipes and channels, which are suitable for the distillation from wine, would become clogged by the glutinous wash of malt or grain distillation. Mr. Eneas Coffey, of Dublin, patented a new apparatus in 1832, on the continuous system, which effected a very large saving of fuel; by causing the condensation of the spirit vapour through the agency of a portion of the cool wash, which thus became partially warmed, and to that extent forwarded in its progress. Coffey's still is now largely used in Scotland, in the distillation of grain whiskey; some of the stills are so large as to produce 3000 gallons per hour. Another kind of still, invented by Stein, is much used in Scotland for malt-whiskey. Most of the Scotch whiskey now sold in England is made from grain by Coffey's apparatus, and becomes marketable by mere dilution; but the malt-whiskey, mostly distilled in small establishments by the old apparatus, contains flavouring ingredients of various kinds. The peat-reek or turf-smoke flavour of some of the whiskey, made illicitly in out-of-the-way places, is, there is reason to believe, more or less imitated in whiskey distilled where no peat is employed—principally because English purchasers like that flavour, as an evidence of genuineness.

The great spirit-distilleries of England, if few in number, and not among the largest of our immense factory establishments, are certainly among those which contribute most amply to the revenue; indeed it may be doubted whether they have any parallel in this particular. In order that every gallon distilled may pay its share of duty, excise officers watch the operations with a closeness unequalled in any other department of British industry. It is difficult to say whether the distiller or the exciseman is more completely the master. Some of the London firms pay more than 300,000*l.* annually each to the revenue; and the Excise insists, not only that all the spirit made shall pay duty, but that the distillery shall be so conducted as to obtain the greatest quantity of spirit from a given quantity of malt or grain; thus the exciseman becomes virtually a chemist as well as a tax-collector. Moreover, the duty is paid per gallon of spirit of a certain defined strength; and the exciseman must be learned on the subject of specific gravity, to see that various degrees of dilution are not produced in such a way as to defraud the revenue. Excisemen, one or more, are never absent from the distillery, day or night, Sunday or week-day; they relieve guard, and one does not depart until his successor arrives. Each exciseman employed knows every vessel on the premises; he has a voice in the number, size, and shape of them; he is empowered to limit the number of openings in the more important vessels, and to trace the course and action of every pipe, valve, cock, and tap connected with each; he has duplicate keys to some vessels, and the *only* key to certain others; he can lock up the furnace doors, and lock up the stills, whenever he deems it his duty so to do; he can require, and does require, that the distilling of the wash into spirit shall not take place in the same week as the brewing of wort into wash; in order that he may know exactly how much wort and wash, as well as spirit, is in the several vessels at one time. He tests the specific gravity of all the liquids as often as he pleases; he requires that the numerous pipes shall be painted, some black, some red, some blue, and some white, in order that he may know which is for the conveyance of wort, which for wash, which for the first spirit, and which for the finished spirit; he demands the aid of ladders and passages to give him access to every part of every piece of apparatus: in short, the master distiller is so thoroughly controlled in all the operations, that nothing but the prospect of large profits, arising out of a large business, would induce a manufacturer to wear such shackles.

It is partly owing to this excise supervision, and partly to the enormous capital necessary, that the number of great distilleries remains pretty equal year after year. The following figures are interesting, showing the influence of different causes on the number of distilleries in different parts of the United Kingdom:—

		1834.	1844.	1854.
England:	Malt distilleries	0	0	0
,,	Grain, or mixed distilleries	12	10	12
Scotland:	Malt distilleries	216	164	140
,,	Grain, or mixed distilleries	23	11	15
Ireland:	Malt distilleries	1	2	0
,,	Grain, or mixed distilleries	80	59	43
		332	246	210

We thus see that, in 1854, there was not one *malt* distillery in England or Ireland; whereas, in Scotland, malt distilleries were nearly tenfold as numerous as those in which grain was employed, or grain mixed with malt. It will fall to be considered under the article SPIRITS, how much is produced yearly down to a much later date than 1854; but it will be useful to show here what was the ratio of production in the three kingdoms in the three years above named:—

	1834.	1844.	1854.
	Gallons.	Gallons.	Gallons.
England	4,600,000	5,800,000	7,300,000
Scotland	9,200,000	7,600,000	10,400,000
Ireland	9,500,000	5,600,000	8,800,000
	23,300,000	19,000,000	26,500,000

England began to increase its relative ratio about the year 1851. To what extent poverty, to what extent temperance advocacy, caused the fluctuations in the Scotch and Irish ratios, this is not the place to discuss. Dividing the quantity of spirits which paid duty, by the number of distilleries known to the excise, it appears that, in 1854, the English distilleries produced 600,000 gallons on an average each, the Irish 200,000, and the Scotch 70,000; showing that the Irish distilleries were, on an average, only about one-third the size of the English, and the Scotch one-third that of the Irish. These ratios, however, may have undergone some modification by 1859; for it is known that there is a tendency to increase the size of the distillery establishments.

The process of distilling, hitherto described, has been that in which grain, either raw or malted, has yielded the saccharine element; but we have now to notice certain recent attempts to produce ardent spirits from *beet-root*.

That this can be done has long been known to chemists, practically in France, theoretically in England. The only question has been, whether beet-root distilling can be profitably conducted. One among many systems of operation patented is that of M. Le Play, depending on the fact that the refuse of the distillery can be profitably applied in the immediate neighbourhood of the distillery itself. In 1857 Mr. Dray, the agricultural implement maker, obtained permission from the Excise to make trial of Le Play's plan in a farm homestead owned by him at Farningham, in Kent. This consent was necessary, owing to the rigorous control exercised by the Excise over all spirit distilleries in this country. At Mr. Dray's homestead, spirit was distilled from the beet-root, and live stock were fed from the refuse. The roots, having been gathered from the fields, were washed, cut into slices, placed in vats, and allowed to ferment for twenty-four hours, the fermentation being aided by a little sulphuric acid. The same liquor was available many times over. The pulp, when removed from the vats, was placed in layers in cylinders, the layers being separated by perforated metal plates. The cylinders were then closed air-tight, and steam was admitted to the bottom of one of them. The steam extracted a juice or watery spirit from the pulp in the first cylinder, and passed thence into a second. The vapour was then condensed by passing through a worm in cold water, and, as a liquid, was received in a vat. While the first cylinder was being emptied and re-filled, steam was admitted to the second and third. The object of this three-fold process was, to make the operation a continuous one, and cause each portion of pulp to be acted on twice over, so as to render the extraction thoroughly complete.

The hopes and expectations relating to this system were thus set forth in a letter to the 'Times,' written by Messrs. Ridley: "It is much to be regretted that misconception prevails respecting the properties of beet-root to yield a fine consumable spirit. In France, during the last three years, millions of gallons have been distilled from this cereal, converted into and freely consumed as cognac brandy. So far this tends to demonstrate its superiority over grain for spirit-making purposes. Beet-root contains from 10 to 12 per cent. of solid saccharine matter, which, when disengaged by maceration and distilled in the ordinary manner, will yield, in good seasons, 25 gallons of proof spirit from one ton of root. The root can be cultivated at a cost of 10*s.* per ton; and allowing its value to be augmented to 20*s.*, or even 30*s.*, when used for distilling purposes, a very handsome profit might be obtained by selling its spirit at 2*s.* per gallon. Besides which, the pulp of the root, after being denuded of its saccharum, is in no way deteriorated as cattle food; on the contrary, some authorities assert that, being partially cooked, it is then more nutritious. Our Inland Revenue laws in many instances are found to operate obnoxiously against native enterprise. Why not allow our farmers freely to distil their produce and apply the refuse to fatten cattle, as is the common order of things on the continent, particularly in Germany. A new field might easily be opened for the cultivation of beet-root, on lands now lying waste, which could be profitably turned to account, to provide spirit for man and food for beast; while the highly-cultivated grain lands could be more exclusively devoted to their legitimate purpose of raising breadstuffs for the actual wants of the community."

This bright picture has hitherto been only a picture: either because the estimates were far beyond the average truth, or because the heavy spirit-duty operates as a bar to improvement in England. The Excise authorities have certainly not been obdurate in the matter. At Farningham, the spirit produced was found to be very raw, but was improved by rectifying; and it was proposed to fix a rectifying apparatus to the stills themselves, so as to complete all the operations on the spot. The spent pulp was said to be worth 15*s.* per ton, to be mixed with cut hay as a food for horses, cattle, and sheep. Listening to the representations made, the Excise, on the authority of the Treasury, permitted eleven more beet-root distilleries to be established in various parts of England. The result, after a year or so, came out as follows:—

	Root distilled.	Spirit obtained.	Produce per ton of root.
	Tons.	Gallons.	Gallons.
Ruddington	517	4631	8·9
Lincoln	600	5710	9·5
Louth	834	4602	5·5
Laxton	397	3435	8·9
Fineshade	515	4201	8·1
Bolney	318	2074	6·5
Minety	759	7003	9·2
Crowmarsh	207	1260	6·0
Reading	460	4395	9·5
Otford	224	1782	7·9
Fulham	70	487	6·9

The produce thus varied from 5¼ to 9¼ gallons per ton, instead of 25 gallons according to the estimate. The Board of Inland Revenue thus reported on the whole subject in 1858 to the Treasury: "Messrs. Dray, who made the apparatus, and are licensed by the patentee of the process, represented to us so strongly the necessity of giving a fair scope to their experiment, by trying it on a large scale, and with the produce of various qualities of soil, that we obtained your lordships' leave (not without first ascertaining that the licensed distillers would have no objection) to permit the erection of twelve beet-root spirit distilleries in different parts of the United Kingdom, the selection of persons and of places being left to Messrs. Dray. Only ten (!) of these distilleries have been in operation; but as none of them have succeeded in producing a saleable spirit, or spirit of any kind in sufficient quantity per ton of root to pay their working expenses according to the calculations of the projectors, it may fairly be assumed that the process can never be successfully adopted in this country. The observations of our officers on the results obtained at each place will be found in the appendix; and it may therefore be sufficient to state here, that one of the most enterprising of these experimentalists has recently applied to the chairman of the Excise for protection against the grain distillers, in the shape of a differential duty of 2s. 6d. in his favour; and has acknowledged that, without some such advantage, it would be impossible for him to make a profit, or even to pay the working expenses of the distillery."

Whether the spirit be obtained from grain, malt, or beet-root, it is generally in too crude and distasteful a state to be used as beverage without further preparation. Whatever may be the case in Ireland or Scotland, the English spirit is always *rectified* before it passes into the hands of the retailer. The great distillers may not rectify their spirit; they must sell it in a crude state—this is a precautionary measure on the part of the Excise. The rectifiers buy the spirit, and convert it into gin, hollands, whiskey, British brandy, British rum, spirits of wine, and such cordials as aniseed, cloves, peppermint, &c. This is done by re-distilling, with water as a diluent; and by further distillation in company with such herbs, spices, seeds, berries, fruits, leaves, perfumes, or sweetening ingredients, as may be necessary to impart flavour. One of these distillations is called *rectifying*, and the other *compounding*. There is no limit to the varieties of flavour that may thus be produced. Spirits of wine contains none of these subsidiary ingredients; it contains only spirit and water, the spirit being strengthened to a great degree of intensity.

A very interesting kind of distilling, whereby sea water is converted into fresh, will be more conveniently treated under FILTER, in connection with other modes of purifying water.

DISTORTION. Deformity of the person may be advantageously classed for the purpose of discussion under two principal heads: *malformation* and *distortion*. The former is, for the most part, congenital, and is usually characterised by the deficiency or redundancy of parts, or by imperfections and irregularities of structure. The latter, arising generally after birth, comprises all permanent deviations from the natural shape or position which are effected by the influence of external or internal force in parts originally soft and flexible, or such as have acquired unnatural pliancy by accident or disease.

It is to the latter class of deformities only that our attention is for the present directed. But even thus limited, the subject is so extensive that we must once for all refer the reader for more precise information on several of its most interesting subdivisions to professional works. [CONTRACTION.]

I. Every part of the body capable of independent motion is furnished with two sets of muscles, acting in contrary directions, the purpose of which is obviously to bring the part back to its place after movement in either direction. In the position of equilibrium these muscles are not in a state of absolute relaxation, even during sleep; on the contrary, they continue to act with considerable energy, each exactly counterbalancing the other. This is called their tone or tension, and it is calculated to give great steadiness to the part thus held at rest between opposite forces. But if one set of the muscles should be suddenly cut across, the tension of their antagonists still remaining in action, the consequence would be a movement in obedience to the latter till the contraction had reached its limit; and the part in question would permanently retain the position into which it had thus been moved. The same effect would result if the muscle, instead of being divided, were paralysed by the interruption of its nervous communication with the brain. Again, if the tone of one muscle were increased by spasm or otherwise, so as to give it a decided preponderance over its antagonist, the result would be similar. These considerations will sufficiently explain the nature of one large class of distortions, namely, those which result from affections of the *brain*, *muscles*, and *nerves*.

1. The simplest of these is the *drawn mouth*, or *hemiplegia*. It arises in this way: in consequence of an extravasation of blood or some other cause, the functions of one side of the brain are interrupted; the muscles of the cheek on the same side, deriving their nerves from that part of the brain, are paralysed, and the retractors on the opposite angle of the mouth being no longer balanced by an equal force, draw it up towards their origin, and retain it in that position.

2. *Strabismus*, or squinting, is frequently produced in the same way by a partial paralysis of that muscle the office of which is to turn the globe of the eye in the opposite direction, or it may arise from undue contraction of the muscle on the same side.

3. It is remarkable that *hysteria* is sometimes accompanied by a distortion of the last mentioned kind, produced by a spasmodic contraction of the flexor muscles of one of the joints, commonly the knee or hip. For months or years this painful condition may last without mitigation: yet it may vanish all at once under the influence of some powerful impression of the body or mind. The entire loss of the voice, which sometimes comes on suddenly in similar constitutions, and after long resisting every remedy, as suddenly departs, is probably an analogous affection of the muscles of the larynx.

4. *Wry-neck* is a distortion also due to irregular muscular action. It generally comes on gradually in infancy, and consists in a shortened and contracted state of the *sterno-mastoid* muscle, of that side to which the head is inclined and *from* which the face is turned. *Club-foot* is often nothing more than a similar contraction of the muscles of the calf, which draw up the heel and eventually disturb the integrity of the ankle joint. This complaint also comes on at an early age, and is sometimes congenital. By proper means they both admit of relief, and often of a cure. [CONTRACTION.]

The list of distortions depending on a morbid condition of the muscular or nervous functions might easily be extended.

II. But by far the most common and important class of these affections is that which originates in disease of the bones.

1. The firmness and rigidity of the bones depends upon the due proportion of the earthy matter, phosphate of lime, that enters into their composition. If the proportion of this ingredient be too great, as in old age, and in the disease called *fragilitas ossium*, they become brittle, and are broken by the slightest causes; if it be too small, they become unnaturally pliant, and are distorted by the pressure of the superincumbent weight, or the contraction of the muscles.

The latter condition is prevalent with other structural changes in the disorder called *rickets*. The medical name of this complaint is *rachitis* (from ῥάχις, the spine), and was given to it by Glisson, who first described it, partly because he conceived the vertebræ to be the bones most commonly implicated; but chiefly, it would appear, from the resemblance to the English name. His doctrine was erroneous; and the error perpetuated by the misnomer has led to serious mistakes in practice as well as theory. The spine is undoubtedly liable to partake with the rest of the skeleton in the morbid condition of rickets, but certainly not in a greater degree than the other bones.

This malady seldom appears within the ordinary period of lactation, or after puberty. It is ushered in and attended throughout by general febrile disturbance, and is closely connected with a peculiar morbid condition of the nutritive functions. The opinion that it is of scrofulous origin has lately been strongly controverted, and does not in reality appear to be well supported by facts. It is most common among the poor, and in closely-peopled districts, as all the diseases of children are; but it is by no means confined to either, or to children whose constitutions are apparently the most feeble in other respects. Indeed it is a frequent remark, that the most robust and powerful men exhibit tokens of having been rickety in their childhood. Among such indications are smallness of the pelvis, with inward or outward curvature and disproportionate shortness of the lower limbs. This sudden check to the development of the skeleton, constantly observed in rickety children, with the distortion arising from the unnatural softness of the bones, is the most usual cause of the short stature, as well as the proverbial ugliness, of dwarfs.

In extreme cases of this complaint the head is generally small and pointed: no longer supported by the yielding and shortened neck, it sinks down between the shoulders; the occiput is thrown back and almost touches the hump formed by the incurvated spine behind the chest: the chin is thrust forward, giving an expression to the features very characteristic of the dwarf, and rests upon the breast bone, which is very prominent: on each side the ribs are flattened, and bulge in upon the lungs. The shoulders, losing the support of the wreathed and twisted clavicles, approach towards each other in front, drawing with them the scapulæ, which stick out laterally, and add considerably to the deformity as seen from behind; the arms, though bent and in reality shortened, seem of disproportionate length; the lumbar spine is thrust inwards; the pelvis is small and flattened; the thighs are bowed forward; the knees with their patellæ at the side instead of in front of the joint, touch or overlap each other; while the feet are set wide apart, a sudden twist above the ankle still permitting the soles to be set to the ground. Such are some of the varied changes which exhibit a melancholy proof of the prevalence of the disease in every part of the bony frame, and almost defy description. Of course such extreme cases of rickety distortion are comparatively rare; yet almost daily instances are seen by those whose duty calls them into the unwholesome courts and alleys of the metropolis, and slighter examples of the affection are extremely common.

Recovery, even from considerable degrees of this affection, is more frequent and rapid than might be imagined; but the pelvis and lower limbs, which as above-mentioned, are the most commonly and extensively implicated, seldom completely regain their natural proportions. This fact, as it regards the female pelvis, is worthy of notice, being the cause of by far the most dangerous kind of difficult parturition. It is in extreme cases of this sort that the Cæsarean section has been practised.

Independently of rickety distortion, there are two other kinds of curvature of the spinal column which demand a brief notice.

The first, which has frequently been mistaken for rachitis, is usually called *lateral* curvature, to distinguish it from the more serious kind of distortion next to be considered, which is called *angular* curvature.

2. Unlike rickets, which almost always commence in infancy or early childhood, lateral curvature of the spine seldom appears before the tenth year. The external deformity consists in the prominence of one hip (generally the right), and elevation of the corresponding shoulder, the blade of which sticks out in unsightly protuberance behind. The opposite hip and shoulder are respectively flattened and depressed; and the symmetry of the chest is destroyed, one side being larger than the other, and both twisted and misshapen. On examination the spine is found to have a double curvature sideways, so as to resemble the letter S, but generally turned the other way, the concavity of the lower curve being on the right, and the upper on the left side. It arises from weakness in the spinal muscles and local elongations of the ligaments of the vertebræ, from the habit of resting the weight in sitting or standing more on one side than the other; and that side is usually the right. The position is more easy than the upright one, and when not corrected by fitting exercise and change in the nature of the employment, it becomes habitual, and the twist of the person permanent and increasing. The subjects of this kind of distortion are chiefly slender and delicate girls in the middle and upper classes, the poor being comparatively exempt. It comes on insidiously, the attention not being awakened by any particular derangement of the health beyond a certain degree of languor and susceptibility of fatigue, and perhaps a sluggish state of the digestion. The first symptom that betrays its presence is usually a tendency of the dress to slip off the left shoulder. It is much promoted by means often used to prevent it, such as confinement and restraint of the person and posture by stays, backboards, high-backed chairs, reclining on a board, and other contrivances to improve the figure, and restrain the development of the natural form; as well as by the sedentary habits and inappropriate exercises of the academy or school-room. Nature is not to be coerced with impunity by fantastic caprices and contrivances: a good figure as well as good health must be found, if anywhere, in the open air of the fields, in loose and easy clothing, and in unrestrained exercise of the limbs, such as children will always adopt, if left to choose for themselves, in ways much better suited to their age and strength than any that can be invented for them.

3. Angular curvature of the spine is a deformity very different in its nature and appearance from the last described. It arises for the most part from ulceration of a scrofulous kind in the bodies of the vertebræ. The support in front being thus lost, the spine is sharply bent forwards so that one or more of the spinous processes project behind, indicating the position of the diseased vertebræ. This complaint is attended with incomplete paralysis of the lower extremities, and is not unfrequently fatal. In case of recovery the bodies of the contiguous vertebræ are approximated and consolidated with what remains of those which were diseased by the deposition of bony matter. It is in this species of spinal complaint only that rest and the recumbent posture are expedient. The observance of these essential precautions, concurrently with other means, frequently brings about a cure; the distortion however is permanent.

Diseases of a similar kind frequently occur in the bones and joints of other parts of the body; they require similar treatment, and are followed by analogous consolidations and distortions.

4. Rheumatism and other disorders, and even common inflammations, occurring in a high degree within the joints or in their neighbourhood, occasionally produce like effects.

III. Distortions are sometimes occasioned by the contraction of other parts than those which are concerned in motion.

1. Such are those of the fingers, which arise from chronic inflammation and permanent contraction of the palmar aponeurosis, or fascia, a strong inelastic and fibrous membrane attached to the projecting points of bone, and stretched beneath the skin of the palm for the protection of the nerves and other soft parts during the act of forcible grasping. There is a similar aponeurosis in the sole of the foot, which is subject, but not so frequently, to the same shortening. Under this division may be also classed those distortions which arise from burns and other extensive destructions and ulcerations of the skin, in consequence of the contraction of the scar in the process of healing. When these injuries take place in front of the neck and face, the resulting deformity is sometimes frightful. The space between the chin and the breast is filled up by a tense discoloured and corrugated cicatrix, which bows the head forward and draws down the features so as to expose the inner surface of the lower eyelid and keep the mouth constantly open. When they occur in the flexures of the joints, as in front of the elbow, the cicatrix extends in the form of a hard and rigid web between the humerus and fore-arm, the joint being permanently bent. Such deformities may sometimes be partly removed by an operation; but it is extremely painful, and often unsuccessful.

2. A slight injury of the face below the eye, or the simple contraction from some other cause of the skin of that part may produce the deformity called *ectropium*, or eversion of the lower lid; and the opposite state of inversion (*entropium* or *trichiasis*) may result from a similar contraction of the edge of the eyelid itself. Severe inflammation, and even blindness, may be the consequence of the latter affection from the friction of the lashes against the globe. Both of these deformities may be remedied by a slight operation.

IV. Another class of distortions may arise from external pressure; as of the bones and cartilages of the chest from tight stays; or of the phalanges of the toes from ill-made shoes. Instances of this kind of distortion must be familiar to all; and call for no particular explanation or remark.

DISTRESS, *districtio* in the jurisprudence of the middle ages, denotes legal compulsion generally, whether ecclesiastical or civil. One mode of compulsion extensively adopted among the nations of Teutonic origin was the taking possession of the whole or a part of the property of the offender or defaulter, and withholding it from him until the requirements of the law had been complied with. This species of distress was called "naam," from nyman, nehman, to take—a verb common to the Anglo-Saxon, German, and other cognate languages. The modern distress is the "naam," restricted to the taking of *personal* chattels; and in its most simple form it may be stated to be—the taking of personal chattels out of the possession of an alleged defaulter or wrong-doer, for the purpose of compelling him, through the inconvenience resulting from the withholding of such personal chattels, to perform the act in respect of which he is a defaulter, or to make compensation for the wrong which he has committed.

Some rights to which the law annexes the remedy by distress, have been considered as too important to be left to the protection afforded by the mere detention of the *distress* (by which term the thing taken is also designated), and more efficacious means of dealing with it have been introduced; and in certain cases a sale of the property taken by way of distress is allowed, if, after a certain interval, the party distrained upon continues to be unwilling or unable to do the act required.

Distresses are either for some duty omitted, some default or nonfeasance,—or they are in respect of some wrongful act done by the distrainee; that is, the person whose goods are distrained upon.

I. *As to distresses for omissions, defaults, or nonfeasance.*—These may be grounded upon non-compliance with some judicial requirements, or they may be made by private individuals in vindication of certain rights, for the withholding of which the law has entrusted them with this remedy.

The process out of courts of record ordering such distresses to be made, is called a writ of *distringas*, which, when legal proceedings were in Latin, was the word used to direct the sheriff or other officer to make the distress.

Another class of judicial distresses is where, upon refusal or omission to pay a sum in which a party is convicted upon a summary proceeding before justices of the peace, such justices are empowered to grant a warrant authorising and directing the levying of the amount by distress and sale of the goods of the offender.

Another species of judicial distress is that awarded and issued upon a judgment recovered in an inferior court, not of record. In these cases the execution or remedy for obtaining payment of the sum recovered is by distress. A precept issues to the officer of the court, commanding him to take the goods of the party, and to impound them until he satisfies the debt. Such process issues at the command of the sheriff, or of the lord of the manor, &c., in whose name and by whose authority the courts are holden.

So a distress lies, subject to certain restrictions, for fines and amercements imposed in the sheriff's tourn and in a court-leet. [LEET; TOURN.]

A penalty inflicted for the breach of a bye-law [BYE-LAW] may be levied by distress, in cases where that remedy is appointed at the time of the making of the particular bye-law. But a bye-law establishing a distress cannot authorise the sale of the distress.

Another species of judicial distress is a distress taken for various rates and legal assessments.

In the foregoing cases the right or duty withheld has been ascertained by some judicial determination before a distress can be resorted to. But many payments and duties having their origin in feudal rights may be enforced by distresses taken by the sole authority of the parties claiming such payments or duties. The rights, of which the vindication is thus in the first instance entrusted to the parties themselves, are connected immediately or mediately with feudal superiority; and it is observable, that to feudal superiority, jurisdiction and magisterial authority were always incident.

Among the feudal duties which may be enforced by distress, at the mere will of the party claiming to be entitled to such duties, one, which though seldom exacted, is still of the most extensive obligation, is fealty. Fealty is a promise, confirmed by an oath, to be faithful in the performance of those engagements into which the party doing the fealty (as the act of taking the oath is termed) has expressly or impliedly entered upon becoming tenant to the party receiving the fealty.

A distress also lies for suit of court, *secta ad curiam*, or the attendance which freehold tenants owe to their lord's court-baron, or freeholders'-court, and which tenants in villenage or copyholders owe to the lord's customary court; and it is not unusual for lessees for years to covenant to attend the lord's courts, though, unless they also fill the situation of freeholders of the manor, they are not qualified to sit as suitors and judges in the court-baron; and unless they are copyholders, they cannot be sworn upon the homage or jury in the customary court. This suit is sometimes called suit-service, to distinguish it from suit real, which is that suit of court which the resiants, or those who dwell within a hundred or a leet, owe to the sheriff's tourn or to the court-leet. [LEET; SUIT.]

A distress lies for suit of mill (*secta ad molendinum*), an obligation, still existing in some manors, to grind at the lord's mill.

So for frankfoldage, or a right in the lord to require his tenants to fold their sheep upon his lands.

So if land be holden by the tenure of repairing a bridge, or a highway, or of doing suit to a leet, or filling some office within the leet, a distress will be for non-performance of the service, although no fine or amercement may have been imposed in the court leet.

The most important feudal duty for which a distress may be taken is *rent*. Rent, in its original and still most usual form, is a payment rendered by the tenant to his landlord as an equivalent or a compensation for the occupation of land, &c. Such rent is denominated rent-service. It comes in lieu of, and represents the profits of the land granted or demised, and is therefore said to *issue* out of the land. To rent-service the law annexes the power of distress, although there be no agreement between the parties creating that remedy. But a rent reserved upon a grant or demise ceases to be a rent-service if it be disannexed from the ultimate property in the land, called in some cases the reversion, in others, the right of reverter. Thus, if the owner of land in fee demises it for a term of years, reserving rent, and afterwards assigns the rent to a stranger, retaining the reversion, or grants the reversion, retaining the rent, the rent being disconnected from the reversion is considered as a branch severed from the trunk, and is called a dry rent or rent-seck, to which the common law annexed no power of distress. So, if the owner of the land, without parting with the land, grants to another a rent out of the land, the grantee having no reversion had only a rent-seck, unless the grant expressly created a power of distress, in which case the rent would be a rent-charge. But now, by statute 4 George II. c. 28, s. 5, the like remedy by distress is given in cases of rent-seck, as in the case of rent reserved upon lease.

And as all rents, though distinguished by a variety of names derived from some particular circumstance attached to them, are resolvable into rent-service, rent-seck, or rent-charge, a distress lies at this day for every species of rent, though a practical difference still subsists as to the mode of dealing with distresses taken for the one or for the other. As to the several species of rent, and as to the creation, transfer, apportionment, suspension, and extinction of rents, and as to the estate or interest of the party necessary to support a distress for rent, and the cases in which this remedy may be exercised by the personal representatives of such parties, see RENT.

A *heriot* appears to have been originally a voluntary gift by the dying vassal to his chieftain or lord (*here*, *heres*) of his best horse or armour. It has now become a legal liability to deliver the best animal of the deceased tenant to be selected by the lord, or sometimes a dead chattel or a commutation in money. Where heriot is due by usage within a particular district, in respect of all tenants dying within that district, without reference to the property held, it is heriot-custom; and as there is no particular land charged with the heriot, the lord cannot distrain, but may seize the heriot as his own *property*, his election being determined by the bare act of seizure. But heriot due in respect of the estate of the tenant in the land is heriot-service; and for this the lord may either distrain upon the land to compel the tenant to deliver or procure the delivery of the heriot due upon the death of his predecessor, or he may choose for himself, and seize the heriot as his own property (the right of property vesting here also upon the election exercised and signified by the seizure).

As heriot is something rendered upon the death of a tenant, so *relief* is a payment made by the heir upon the taking up (*relevatio*) by him of the inheritance. Strictly speaking, relief was payable in those cases only where the tenure was by knight's service. But the name was afterwards extended to a payment in the nature of a relief made by the heir in socage, by doubling the rent for the first year after the descent of the land,—in other words by paying one year's additional rent. For this latter payment a distress still lies.

Toll is a charge or impost upon goods in respect of some benefit conferred or right forborne with relation to those goods, by the party claiming such toll.

Tolls of fairs or *markets* are a duty payable to the owners of the fair or market as a compensation for the mischief done to the soil by the holding of such fair or market.

Toll-traverse is a compensation paid in some cases to the owner of the soil in respect of the transit or passage of goods.

Toll-thorough is a toll for the transit of goods along a street or highway repaired by the party claiming the toll.

Port-tolls, more commonly called *port-duties*, are tolls payable in respect of vessels coming to or sailing from a port or a wharf of which the parties claiming the tolls, or those from whom they derive their title to such tolls, are the owners.

In all these cases, if the toll be withheld, any part of the property chargeable therewith may be seized and detained as a pledge for the payment of such toll.

II. *Distress for things damage feasant.*—Besides distresses for omissions, defaults, or nonfeasance, this remedy is given in certain cases as a mode of obtaining reparation for some wrong done by the distrainee. Cattle or dead chattels may be taken and detained to compel the payment of a reasonable sum of money by way of satisfaction for the injury sustained from such cattle or dead chattels being wrongfully upon property in the occupation of the party taking them and doing damage there, either by acts of spoliation or merely by encumbering such property. This is called a distress of things taken damage feasant (doing damage).

The occupier of land, &c., is allowed not only to defend himself from injury by driving out or removing the cattle, &c., but also to detain the thing which did the injury till compensation be made for the trespass; for otherwise he might never find the person who had occasioned the trespass. Upon referring to Spelman and Ducange, it will be seen that a similar practice obtained on the continent amongst the Angli, Werini, Ripuarii, and Burgundians.

The right to distrain damage-feasant is given to all persons having an immediate possessory interest in the soil or in its produce, and whose rights are therefore invaded by such wrongful intrusion. Thus, not only the occupier of the land trespassed upon, but other persons entitled to share in the present use of the land or of the produce, as commoners, &c., may distrain. But though a commoner may always distrain the cattle, &c., of a stranger found upon the common, it would seem that he cannot, unless authorised by a special custom, distrain the cattle, &c., of the person having the actual possession of the soil. Nor can he distrain the cattle of another commoner who has stocked beyond his proportion, unless the common be stinted, that is, unless the proportion be limited to a certain number. In the more ordinary case of rights of common in respect of all the cattle which the commoner's enclosed land can support during the winter, cattle exceeding the proportion cannot be distrained.

Cattle found trespassing may be distrained damage feasant, although they have come upon the land without the knowledge of their owner and even through the wrongful act of a stranger. But if they are there by the default of the occupier of the land, as by his neglecting to repair his fences, or to shut his gates against a road or a close in which the cattle lawfully were, such negligent occupier cannot distrain unless the owner of the cattle suffer them to remain on the land after notice and time given to him to remove them; and if cattle trespass on one day and go off before they are distrained, and are taken trespassing on the same land on another day, they can be detained only for the damage done upon the second day.

Cattle, if once off the land upon which they have trespassed, though driven off for the purpose of eluding a distress, cannot be taken even upon immediate pursuit. The occupier is left to his remedy by action.

III. *What may be distrained.*—In distresses for rent and other duties, that which is taken must be something in which a valuable property may exist. But animals of a wild nature, if reclaimed and become valuable (as deer kept in a private park), may be distrained.

Fixtures, not being personal chattels, are not subject to distress. Nor were growing crops subject to distress by the common law; but now, by 11 Geo. II. c. 19, s. 8, distress for rent-service may be made of all sorts of corn and grass, hops, roots, fruit, pulse, or other product whatsoever growing in any part of the land demised.

By the common law nothing could be distrained upon for rent or other duty that could not be restored in as good plight as at the time of the distress being taken; and therefore fruit, milk, and other matters of a perishable nature could not be distrained, nor money unless in a bag, because the identical pieces could not be known so as to be restored to the distrainee; nor could grain or flour be taken if out of the sack, or hay not being in a barn, or corn in the sheaf, because the quantity could not be easily ascertained; and they might be scattered or injured by the removal. None of these could be taken as a distress except for damage-feasant, though the same articles when contained in bags, boxes, carts, or buildings might be distrained upon for rent. But now by 2 Will. & Mary, sess. 1, c. 5, s. 3, distress may be made of sheaves or cocks of corn, or corn loose or in the straw, or hay lying or being in any barn or granary, or upon any hovel, stack, or rick, or otherwise, upon any part of the land.

Where a stranger's cattle are found upon the tenant's land they may be distrained upon for rent-service, provided they are there by the act or default of the owner of such cattle. If they come upon the land with the knowledge of their owner, or by breaking fences which are in repair, or which neither the landlord nor the tenant is bound to repair, they are immediately distrainable; but if they come in through defect of fences which the lord or tenant is bound to repair, the lord cannot take them for rent reserved upon a lease until they have lain for a night upon the land, nor until after notice given to the owner, if he can be discovered, to remove them. But in the case of a lord not bound to repair the fences distraining for an ancient rent or service, and also in the case of a rent-charge, the cattle may be taken, after they have lain a night upon the land, without notice to their owner.

Things necessary for the carrying on of trade, as tools and utensils,—

or for the maintenance of tillage, as implements of husbandry, beasts of the plough, and sheep as requisite to manure the land, are privileged from distress whilst other sufficient distress can be found. But this rule does not extend to a distress for a toll or duty arising in respect of the thing taken as a distress, or of things connected with it; as a distress of two sheep for market-toll claimed in respect of the whole flock, or of the anchor of a ship for port-duty due in respect of such ship.

For the protection of tradesmen and their employers in the necessary transactions of society, property of which the distrainee has obtained the possession with a view to some service to be performed upon it by him in the way of his trade, is absolutely privileged from distress; as a horse standing in a smith's shop to be shod, or put up at an inn, or cloth sent to a tailor's shop to be made into clothes, or corn sent to a mill or market to be ground or sold. The goods of a guest at an inn are privileged from distress; but this exemption does not extend to the case of a chariot standing in the coach-house of a livery-stable keeper; nor does it protect goods on other premises belonging to the inn but at a distance from it; and even within the inn itself the exemption does not extend to the goods of a person dwelling there as a tenant rather than a guest. Goods in the hands of a factor for sale are privileged from distress; so goods consigned for sale, landed at a wharf, and placed in the wharfinger's warehouse.

Beasts of the plough may be distrained where no other distress can be found. And it is sufficient if the distrainor use diligence to find some other distress. A distress is not said to be found unless it be accessible to the party entitled to distrain, the doors of the house being open, or the gates of the fields unlocked. Beasts of the plough may be distrained upon where the only other sufficient distress consists of growing crops, which though now subjected to distress, are not, as they cannot be sold until ripe, immediately available to the landlord.

A temporary privilege from distress arises when the chattel is in actual use, as an axe with which a man is cutting wood, or a horse on which a man is riding. Implements in trade, as frames for knitting, weaving, &c., are absolutely privileged from distress whilst they are in actual use, otherwise they may be distrained upon if no other sufficient distress can be found.

By 7 Ann. c. 12, s. 3, process whereby the goods of any ambassador or other public minister of any foreign prince or state, or of their domestic servants, may be distrained, seized, or attached, is declared to be null and void. But the privilege of a domestic servant of an ambassador does not invalidate a distress for the rent, rate, or taxes of a house occupied for purposes unconnected with the service.

By the Bankrupt Law Consolidation Act, 12 & 13 Vict. c. 106, s. 129, no distress for rent made and levied after an act of bankruptcy upon the goods of any bankrupt shall be available for more than one year's rent accrued prior to the date of the filing the petition; but the party to whom the rent is due shall be allowed to come in as a creditor for the overplus of the rent due, and for which the distress shall not be available.

Where a tenancy for life or at will is determined by death, or by the act of the landlord, the tenant, or his personal representatives, may reap the corn sown before such determination, and therefore such corn though sold to a third person, cannot be distrained upon for rent due from a subsequent tenant. [Emblements.]

Neither the goods of the tenant nor those of a stranger can be distrained upon for rent if they are already in the custody of the law, as if they have been taken damage-feasant, or under process of execution. But although the landlord cannot distrain, yet by 8 Ann. c. 14, he has a lien or privilege upon the goods of his tenant taken in execution for one year's rent. [Execution.]

IV. *Time of making a distress.*—Rent is not due until the last moment of the day on which it is made payable. No distress therefore can be taken for it until the following day. And as a continuing relation of landlord and tenant is necessary to support a distress for rent service, there could at common law be no distress for rent becoming due on the last day of the term. But now, by 8 Ann. c. 14, ss. 6 and 7, any persons having rent in arrear upon leases for lives, for years, or at will, may, after the determination of such lease, distrain for the arrears, provided that such distress be made within six calendar months after the determination of the lease and during the continuance of the landlord's title or interest, and the possession of the tenant from whom such arrears are due. If the possession of the tenant continue in fact, it is immaterial whether that possession be wrongful and adverse, or whether it continues by the permission of the landlord; and if a part only of the land remain in the possession of the tenant, or of any person deriving his possession from the tenant, a distress for the whole of the arrears may be taken in such part during the six months. Where a tenant is entitled by the terms of his lease, or by the custom of the country, to hold over part of the land or buildings for a period extending beyond the nominal term, the original tenancy will be considered as continuing with reference to the land, &c., so retained, and the landlord may distrain at common law for the arrears during such extended period in the lands, &c., so held over, and he may distrain under the statute during six months after such partial right of possession has entirely ceased.

When different portions of rent are in arrear, the landlord may distrain for one or more of those portions, without losing his right to take a subsequent distress for the residue; so, although the first distress be for the rent last due. But if there be a sufficient distress to be found upon the premises, the landlord cannot divide a rent accruing at one time into parts, and distrain first for a part and afterwards for the residue. If, however, he distrain for the entire rent, but from mistaking the value of the goods takes an insufficient distress, it seems that a second distress for the deficiency will be lawful, although there were sufficient goods on the premises to have answered the whole demand at the time of the first taking; and it is clear that he may take such second distress upon goods which have come upon the premises subsequently to the first taking, if in the first instance he distrain all the goods then found thereon and for the entire rent, the amount of which exceeds the value of the goods first taken.

A distress for rent or other duties or services can be taken only between sunrise and sunset; but cattle or goods found damage-feasant may be distrained at any time of the day or night.

By the common law the remedy by distress was in general lost upon the death of the party to whom it accrued. But the king and corporations aggregate never die; and as the law authorises a surviving joint tenant to act as if he had been originally the sole owner, he may distrain for rent or other services accruing in the lifetime of his companion.

The statutes of 32 Hen. VIII. c. 37, and 3 & 4 Will. IV. c. 42, have extended the remedy by distress to husbands and executors in respect of rent accruing due to their deceased wives or testators. [Rent.]

No distress can be taken for more than six years' arrears of rent; nor can any rent be claimed where non-payment has been acquiesced in for twenty years, 3 & 4 Will. IV. c. 27.

V. *In what place a distress can be made.*—The remedy being given in respect of property, not of the person, a distress for rent or other service could at common law be taken only upon the land charged therewith, and out of which such rent or services were said to issue.

But this restriction did not apply to the king, who might distrain upon any lands which were in the actual occupation of his tenant, either at the time of the distress or when the rent became due.

The assumption of a similar power by other lords was considered oppressive, and it was ordained by the statute of Marlbridge, that no one should make distress for any cause out of his fee, except the king and his ministers thereunto specially authorised. The privilege of distraining in all lands occupied by the party chargeable, is communicated by 22 Car. II. c. 6; 26 Geo. III. c. 87; 30 Geo. III. c. 50; and 34 Geo. III. c. 75, to the purchasers of certain crown rents.

At common law if the tenant or any other person seeing the lord or his bailiff come to distrain for rent or other service, drove the cattle away from the land holden, they might be distrained off the land. Not so when the cattle without being driven went off before they were actually taken, though the lord or bailiff saw the cattle upon the land (which for some purposes is a constructive possession). Nor if after the view the cattle were removed for any other purpose than that of preventing a distress. On the other hand, cattle of which the lord or bailiff has no view whilst they are on the land, although the tenant drove them off purposely to avoid a distress, could not be distrained.

Under 8 Ann. c. 14, and 11 Geo. II. c. 19, where a lessee fraudulently or clandestinely carries off his goods in order to prevent a distress, the landlord may within five days afterwards distrain them as if they had still continued on the demised premises; provided they have not been (*bonâ fide*) sold for a valuable consideration.

And by the 7th section of the latter statute, where any goods fraudulently and clandestinely carried away by any tenant or lessee, or any person aiding therein, shall be put in any house or other place, locked up or otherwise secured, so as to prevent such goods from being distrained for rent, the landlord or his bailiff may, in the day time, with the assistance of the constable or peace officer (and in case of a dwelling-house, oath being also first made of a reasonable ground to suspect that such goods are therein), break open and enter into such house or place, and take such goods for the arrears of rent, as he or they might have done if such goods had been put in an open field or place.

To entitle the landlord to follow the goods, the removal must have taken place after the rent became due, and for the purpose of eluding a distress. It is not however necessary that a distress should be in progress, or even contemplated. Nor need the removal be clandestine. Although the goods be removed openly, yet if goods sufficient to satisfy the arrears are not left upon the premises, and the landlord is turned over to the barren remedy by action, the removal may be by a jury deemed fraudulent, and the provisions of these statutes will then apply. The goods of a stranger or of an under-tenant may be removed at any time before they are actually distrained upon, and cannot be followed.

Where two closes are let by separate demises and separate rents, though such demises be made at the same time, and are even contained in the same deed, a distress cannot be taken in one close for both rents.

If a rent-charge or rent-service also issue out of land which is in the hands or separate possession of two or more persons, a distress may be taken for the whole rent upon the possession of any one of them.

The lord may enter a house to distrain if the outer door be open, although there be other sufficient goods out of the house. It is not lawful to break open outer doors or gates; but if the outer door be open, an inner door may be forced. And where the lord having distrained is forcibly expelled, he may break open outer doors or gates in order to retake the distress. If a window be open, a distress within reach may be taken out at it.

At common law a distress might be taken for rent in a street or other highway being within the land demised. But now, by the statute of Marlbridge, private persons are forbidden to take distresses in the highway. This statute applies only to distresses for rent or for services, and not to toll. Nor does the statute make the distress absolutely void; for though the tenant may lawfully rescue cattle distrained in the highway, or may bring his action on the case upon the statute, yet if he brings trespass or replevin, it seems to be no answer to a justification or an avowry made in respect of the rent.

No rent can be reserved out of an incorporeal hereditament; and therefore at common law the lord could not distrain for rent in a place in which the tenant had merely an incorporeal right—as a right of common. By 11 Geo. II. c. 19, s. 8, landlords are enabled to take a distress for rent upon cattle belonging to their tenants feeding upon any common appendant or appurtenant to the land demised. But in cases not within this enactment, the rule of the common law applies; and therefore upon a demise of a wharf and the appurtenances, with liberty to land and load goods, the landlord cannot distrain the tenant's barges lying opposite and attached to the wharf.

VI. *Mode of making a distress.*—A distress may be made either by the party himself or his agent, and as distresses in manors were commonly made by the bailiff of the manor, any agent authorised to distrain is called a bailiff. The authority given to the bailiff is usually in writing, and is then called a warrant of distress; but a verbal authority, and even the subsequent adoption of the act by the party on whose behalf the distress is made, is sufficient. In order that the distrainee may know what is included in the distress, an inventory of the goods should be delivered, accompanied, in the case of a distress for rent, by a notice stating the object of the distress, and informing the tenant that unless the rent and charges be paid within five days, the goods and chattels will be sold according to law. This notice is required by 2 Will. & Mary, sess. 1, c. 5, s. 2, which enacts, "that where any goods shall be distrained for rent due upon any demise, lease, or contract, and the tenant or owner of the goods shall not, within five days next after such distress taken, and notice thereof with the cause of such taking, left at the chief mansion house, or other most notorious place on the premises, replevy the same, with sufficient security to be given to the sheriff,—that after such distress and notice and expiration of the five days, the person distraining shall and may, with the sheriff or under-sheriff, or with the constable of the place, cause the goods to be appraised by two sworn appraisers, and after such appraisement may sell the goods distrained towards satisfaction of the rent, and of the charges of distress, appraisement, and sale, leaving any surplus in the hands of the sheriff, under-sheriff, or constable, for the owner's use."

At common law, goods distrained were, within a reasonable time, to be removed to and confined in an enclosure called a pound, which is either a pound covert, that is, a complete enclosure, or a pound overt, an enclosure sufficiently open to enable the owner to see, and, if necessary, to feed the distress, the former being proper for goods easily removed or injured, the latter for cattle; and by 5 & 6 Will. IV. c. 59, s. 4, persons impounding cattle or animals in a common open or close pound, or in enclosed ground, are to supply them with food, &c., the value of which they may recover from the owner. By 11 Geo. II. c. 19, s. 10, goods distrained for any kind of rent may be impounded on any part of the tenant's ground, to remain there five days, at the expiration of which time they are to be sold, unless sooner replevied. The landlord is not however bound to remove the goods immediately after the expiration of the five days; he is allowed a reasonable time for selling. After the lapse of a reasonable time he is a trespasser if he retain the goods on the premises without the express assent of the tenant, which assent is generally given in writing.

The 1 & 2 Phil. and Mary, c. 12, requires that no distress of cattle be removed out of the hundred, except to a pound overt in the same county, not above three miles from the place where such distress is taken, and that no cattle or other goods distrained at one time be impounded in several places, whereby the owner would be obliged to sue out several replevins.

The 2 Will. & Mary, sess. 1, c. 5, s. 3, directs that corn, grain, or hay distrained be not removed, to the damage of the owner, out of the place where the same shall be found or seized, but be kept there until replevied or sold; and 11 Geo. II. c. 19, which gives a distress for rent-service upon growing crops, directs, ss. 8 and 9, that they shall be cut, gathered, and laid up, when ripe, in the barn or other proper place on such premises, or if none, then in some other barn, &c., to be procured for that purpose, and as near as may be to the premises, giving notice within one week of the place where such crops are deposited; and if the tenant, his executors, &c., at any time before the crops distrained are ripe and cut, pay or tender the rent, costs, and charges, the goods distrained are to be restored. In all other cases, if the rent or other duty be paid or performed, or tendered to be paid or performed before the distress is impounded, a subsequent detainer is unlawful, and a subsequent impounding or driving to the pound is a trespass.

The statutes authorising the sale of distresses extend only to those made for rent, and to those made for rates and other legal assessments. At common law distresses cannot in general be either sold or used for the benefit of the party distraining. But a distress for fines and amerciaments in a court leet, or for other purposes of public benefit, may be sold; and a special custom or prescription will warrant the sale of a distress in cases where the public has no immediate interest.

VII. *Rights and remedies of the distrainee.*—A distress made by a party who has no right to distrain, or made for rent or other service which the party offers to pay or perform, or made in the public highway, or upon goods privileged from distress either absolutely or temporarily, is called a *wrongful distress.* Where no right to distrain exists, or where the rent or duty is tendered at the time of the distress, the owner of the goods may rescue them or take them forcibly out of the possession of the distrainor, or bring an action of replevin, or of trespass, at his election. In replevin, the cattle or goods taken are to be re-delivered to the owner upon his giving security by a replevin bond, for returning them to the distrainor, in case a return shall be awarded by the court; and therefore, in this action, damages are recovered only for the intermediate detention and the costs of the replevin bond. [REPLEVIN.] In the action of trespass, the plaintiff recovers damages to the full value of the goods; because, upon such recovery, the property in the goods is transferred to the defendant.

The 2 Will. & Mary, sess. 1, c. 5, s. 5, provides "That in case of any distress and sale for rent pretended to be due, where in truth no rent is due, the owner of the goods so distrained and sold may, by action of trespass or upon the case, recover double the value of such goods, with full costs of suit."

For a wrongful distress in taking goods protected by being in a street or highway, or goods privileged from distress, the remedy is by an action on the statute, in which the plaintiff is entitled to an immediate return as in replevin.

If the cattle or goods distrained cannot be found, the sheriff may take other cattle or goods in wither nam (by way of counter-distress) of the same or of a different kind, belonging to the distrainor, and deliver them to the distrainee instead of his own.

Another species of wrongful distress is *re-caption*, or the taking of the same or other goods of the distrainee for the same causes pending an action of replevin, in which the legality of the first distress is questioned.

Wherever a distress is wrongful, the owner of the goods may rescue them from the distrainor; but after they are actually impounded, they are said to be in the custody of the law, and must abide the determination of the law.

Whether goods are rightfully or wrongfully distrained, to take them out of the pound is a trespass and a public offence. The proceeding by action is a more prudent course than making a rescue, even before an impounding, where any doubt exists as to the lawfulness of the distress. Independently of the danger of provoking a breach of the peace by the rescuer's thus taking the law into his own hands, he will be liable to an action for the injury sustained by the distrainor by the loss of the security of the distress, should the distress ultimately turn out to be lawful; and in such action, as well as in the action for pound-breach, the rescuer will be liable, under 2 Will. & Mary, sess. 1, c. 5, s. 4, to the payment of treble damages.

A distress for more rent, or greater services than are due, or where the value of the property taken is visibly disproportionate to the rent or other appreciable service, is called an *excessive distress,* for which the party aggrieved is entitled to recover compensation in an action; but he cannot rescue, nor can he replevy or bring trespass.

Upon a distress rightfully taken being afterwards irregularly conducted, the subsequent irregularity at common law made the whole proceeding wrongful, and the party was said to be a trespasser *ab initio.* But now, by 11 Geo. II. c. 19, where distress is made for rent justly due, and any irregularity or unlawful act is afterwards done by the party distraining, or his agent, the distress itself is not to be deemed unlawful nor the party making it a trespasser; but the person aggrieved by such irregularity, &c., may recover satisfaction for the special damage sustained. And see Bracton; Fleta; Coke upon Littleton; Bacon, Comyns, and Viner's 'Abridgments;' and Blackstone's 'Commentaries,' by Dr. Kerr.

DISULPHETHYLIC ACID. [ETHIONIC ACID].

DISULPHONAPHTHALIC ACID. [NAPHTHALIC GROUP.]

DITCH. [BASTION.]

DITHIOBENZOLIC ACID ($C_{12}H_8N_2S_4O_{10}$, 2HO). A product of the action of sulphite of ammonia on dinitrobenzole. It is bibasic and cannot be isolated from its salts.

DITHIONIC ACID. [SULPHUR, *Hyposulphurous Acid.*]

DITHYRAMBUS, the name of a hymn in honour of Dionysus, sung by a chorus of fifty men or boys as they danced round the blazing altar of the god; from this peculiarity it was also called the *cyclic* or *circling* chorus. The original subject of the song was the birth of

Dionysus, as the name seems to have implied. (Plato, 'Legg.' iii.) The music was Phrygian, and the accompaniment originally the flute. (Aristot., 'Polit.' viii. 7, 9.) The Dithyrambus is particularly interesting from the circumstance that Aristotle attributes to it the origin of the Greek tragedy. "Tragedy and comedy," says he ('Poet.' iv. 14), "having originated in a rude and unpremeditated manner, the first from the leaders in the Dithyrambic hymns, the other from the Phallic songs, advanced gradually to perfection." These leaders (ἐξάρχοντες), and not, as has been wrongly inferred from the words of Aristotle, the whole chorus, recited trochaic tetrameters, and are to be considered as the immediate predecessors of the actors. [DRAMA.] In the Appendix to Walker's Treatise on the Trilogy ('Nachtrag zur Schrift über die Æschylische Trilogie,' p. 228 and following), the reader will find a learned disquisition on the Dithyrambus, deformed however by some serious errors. After the leading properties of the Dithyrambus had merged in the Greek tragedy, it became very bombastic, and in the Greek, and even in modern languages, the epithet Dithyrambic is a synonym for turgid and hyperbolical expressions. The etymology of the word is unknown.

DIURETICS are agents which augment the urinary secretion and facilitate its expulsion from the bladder. They constitute an extensive class of substances which, however, are very uncertain in their action, and require to be varied very frequently on account of the effects which their long continued use produces on the stomach and digestive function. The uncertainty of their operation is owing probably less to causes inherent in them than to our want of acquaintance with or attention to the circumstances which influence their action. Some writers disavow their belief in the existence of a distinct class of substances entitled to be called diuretics, considering them as mere general stimulants; but such a view is inadmissible, as many of them, far from being stimulants, are decidedly sedative, while some of the feelings which cause diuresis, such as fear or terror, and the external application of cold, are likewise sedative in their effects on the system.

In attempting to ascertain or account for their mode of action, we must constantly bear in mind the nature of the functions of the kidneys, namely, not only to remove from the body a considerable quantity of its fluid contents, but at the same time a great number of saline and other principles, the retention of which, for any considerable time, in the system, causes serious departure from its healthy state, and in some instances speedy death. Not only therefore must the quantity of fluid eliminated be in due proportion, but the quality or chemical constitution of it must also be of a proper kind. Any variation in these conditions requires the interference of medicine to rectify it. In endeavouring to accomplish this object, it must be borne in mind that, according to the state of the system, sometimes an acid diathesis predominates, sometimes an alkaline. The means which we employ to attain our object may be classified according to their primary modes of action on the system. Some are stimulant, such as gamboge, cytisus scoparius, alcohol, spiritus ætheris nitrici, oil of juniper, oil of turpentine, &c. Some, again, are sedative, such as lactuca virosa, leontodon taraxacum, digitalis, squil, colchicum, &c.: others are refrigerant, of which some render the urine acid, such as the dilute mineral acids; some, on the opposite hand, render the urine alkaline, such as the carbonate of potass, acetate, tartrate and bitartrate of potass; while certain saline diuretics do not render it either acid or alkaline, such as nitrate of potass, biborate of soda, &c.

The more acrid diuretics seem to act upon the lower sphere of life, or what may be considered the vegetative system, such as the cellular tissue, the fatty structures, and the internal mucous coats, the secretion of which they render thinner as well as more abundant, but at the same time they interfere much with the assimilative process as well as with that of digestion, even when given in small doses; and hence arises the impossibility of prolonging their employment beyond a very limited time. Whatever be the agent we select it is by no means necessary that, to cause a diuretic effect, the substance should be decomposed; but it is important to remember that, when saline diuretics are decomposed, the alkali is carried to the kidneys as the emunctory by which it is to be ejected from the system, and hence their use speedily renders the urine alkaline, which, when in a high degree, may prove very hurtful to the system generally, and to the bladder and urinary passages in particular.

Numerous as are the agents termed diuretics, none of them will act as such unless the patient be under certain conditions. If a very inflammatory state of the system exist, no article will act as a diuretic till this be lessened, and hence the necessity of employing venesection and saline cathartics before administering any of the class of diuretics; and under such circumstances colchicum is perhaps the best to begin with. Even such inflammation as exists in some forms of dropsy must be removed by antiphlogistic means before diuretics will have a beneficial effect (Blackhall 'on Dropsy'); particularly after scarlatina, with albuminuria.

When a very great quantity of fluid is present in the body, some of it must be carried off by other means before diuretics can act, as the absorbents under such circumstances do not furnish a supply to the kidneys—the activity of absorption being always in an inverse ratio to the smallness of the quantity of fluid present. (Majendie.) If there be great general debility of the system, and particularly of the absorbents, this state must be obviated either by the exhibition of tonics previous to or along with the diuretic remedies. Lastly, none of the saline diuretics, which are susceptible of decomposition, will act, if any considerable catharsis be going on, and hence that action, if arising from other causes, should be moderated or checked; and care should be taken not to exhibit such of them as are also purgatives in such doses as to act upon the bowels. This observation is not intended to prohibit the exhibition of a single purgative previous to commencing the use of diuretics, as this is often beneficial, or to forbid their occasional use when required to obviate particular symptoms. It must never be forgotten that if the patient be kept very warm, the action will more probably be directed to the skin than to the kidneys; hence the patient should not, if possible, remain in bed: the medicines should be given during the day, and the air of the apartment should be cool, and the clothing light. Indeed cold itself is a powerful diuretic, and sometimes succeeds where every other fails. The drinking of diluents likewise promotes the action of the kidneys; it is therefore unwise as well as cruel to withhold water from dropsical patients. [DILUENTS.]

The wines of the Rhine, Maine, and above all, of the Moselle, are powerful diuretic drinks, and their use tends much to diminish the liability to stone in the bladder. (Liebig.) [WINE.] But to do good, these wines should mostly be used habitually—and alone, not mixed or alternated with other wines.

Diuretics are by no means sufficiently employed as general curative agents, particularly in chronic diseases. In many cutaneous diseases of an obstinate kind they are very valuable; the vicarious nature of the functions of the skin and the kidneys pointing the one out as the appropriate substitute for the other.

DIVAN or DÎWÂN, is a Persian word familiar to readers of works relating to the East, in the sense of—1st, a senate, or council of state; and, 2nd, a collection of poems by one and the same author. The earliest acceptation, however, in which we find it employed is that of a muster-roll, or military pay-book. The Arabic historian, Fakhreddin Râzi informs us that when, in the caliphat of Omar, the second successor of Mohammed, the conquests of the Mussulmans assumed an extensive character, the equal distribution of the booty became a matter of great difficulty. A Persian marzbân, or satrap, who happened to be at the head-quarters of the caliph at Medinah, suggested the adoption of the system followed in his own country, of an account-book, in which all receipts and disbursements were regularly entered, along with a list duly arranged, of the names of those persons who were entitled to a share in the booty. With the register itself, its Persian appellation (dîwân) was adopted by the Arabs. (Freytag, 'Locmani Fabulæ et plura loca ex codd. historicis selecta,' &c., pp. 32, 33; Henzi, 'Fragmenta Arabica,' St. Petersburg, 1828, p. 36, *et seq.*) Whether a council of state was subsequently called divan, as having originally been a financial board appointed to regulate the list (dîwân) of stipendiaries and pensioners, or whether it was so called as being summoned according to the list (dîwân) containing the names of all its members, we are unable to determine. The opinion that a body of councillors should have received this appellation, as has been asserted by some, in consequence of the expression of an ancient king of Persia, *înân dîwân end,* "these (men) are (clever like) devils," will scarcely be seriously entertained by any one. The word "dîwân" is also used to express the saloon or hall where a council is held, and has been applied to denote generally a state chamber, or room where company is received. Hence probably it has arisen that the word "divan," in several European languages, signifies a sofa. The divan of the present empire of Turkey consists of the grand vizir, or prime minister; the grand mufti, or head of the church; the seraskier pasha, or minister of war; the tyrdji pasha, commander of the artillery; the capudan pasha, commander of the navy; the reis effendi, or oumouri kharjieh naziri, minister for foreign affairs; the kiaya bey, or oumouri milkieh naziri, minister of the interior; the three ministers of finance, commerce, and police; the president of the council; the master of the mint; and the comptroller general of ecclesiastical property. Each of these dignitaries bears the title of mushir.

Collections of poems in Persian, Arabic, Turkish, Hindustani, &c., seem to have received the appellation "dîwân" from their methodical arrangement, inasmuch as the poems succeed one another according to the alphabetic order of the concluding letters of the rhyming syllables, which are the same in all the distichs throughout each poem.

DIVERGENCY, DIVERGENT. [CONVERGENT.]

DIVIDED EYE-GLASS MICROMETER. [MICROMETER.]

DIVIDEND, in arithmetic, any quantity which is to be divided (*dividendum*). Thus, in the sentence "100 divided by 20 gives 5," the dividend is 100.

DIVIDEND, in commerce, is a word having two distinct meanings. In its more general employment, it is understood to express the money which is divided, *pro rata*, among the creditors of a bankrupt trader, out of the amount realised from his assets. [BANKRUPT.]

The other meaning attached to the word dividend is not so appropriate as that which has just been explained. It is used to signify the half-yearly payments of the perpetual and terminable annuities which constitute the public debt of the country, and does not therefore strictly express that which the word is made to imply. The payment of those so-called dividends is managed on the part of the government by the Bank of England, which receives a compensation from the public for the trouble and expense attending the employment.

DIVIDING ENGINE. [GRADUATION.]

DIVING-BELL. Much ingenuity has been devoted from an early period to the contrivance of apparatus for enabling men to dive, or descend beneath the surface of water, to a greater depth, for a longer space of time, and with less exertion and danger, than is possible by the unassisted powers of the body. The fatal consequences of continued submersion are described under ASPHYXIA and DROWNING; and from the facts there stated it is evident that about half a minute is the longest period during which most individuals can safely remain under water, without some provision for the supply of air for respiration. Experienced divers may remain under water much longer, though not without great and painful exertion; but the longest period of submersion, with a few extraordinary exceptions, does not exceed two minutes; a space of time too brief to allow the performance of any but the simplest operations beneath the surface of the water. The pearl-fishery affords the most prominent example of the employment of divers unassisted by apparatus for providing a supply of air. The mode of diving adopted, and the effects of protracted submersion upon the divers, are described under PEARL FISHERY. Professor Beckmann alludes to the employment of divers in ancient times to assist in raising anchors, in recovering goods from wrecks, or such as had been thrown overboard in times of danger, and in destroying the works and ships of the enemy in time of war, as well as in fishing for pearls; but some of the statements quoted by him are evidently much exaggerated, as they speak of divers remaining for hours under water. Six minutes is about the longest time of submersion of which any authentic account has appeared in modern times. [PEARL FISHERY.]

Dr. Halley, in a paper printed in No. 349 of the 'Philosophical Transactions' (vol. xxix., p. 492), entitled 'The Art of Living under Water,' observes that the divers for sponges in the Archipelago were accustomed to take down in their mouths a piece of sponge soaked in oil, by which they were enabled to dive for a longer period than without it. As the bulk of the sponge must diminish the quantity of air which the diver could contain in his mouth, it does not appear probable that this practice could assist respiration.

In connection with diving by the unassisted powers of the body, allusion may be made to a curious and important fact related in the 'Encyclopædia Britannica,' on the authority of Professor Faraday, to whom it was first noticed by a gentleman connected with the Asiatic Society. The lungs are, in their natural state, charged with a large quantity of impure air; this being a portion of the carbonic acid gas which is formed during respiration, but which, after each expiration, remains lodged in the involved passages of the pulmonary vessels. By breathing hard for a short time, as a person does after violent exercise, this impure air is expelled, and its place is supplied by pure atmospheric air, by which a person will be enabled to hold his breath much longer than without such precaution. The writer states that although he could only hold breath, after breathing in the ordinary way, for about three quarters of a minute, and that with great difficulty, he felt no inconvenience, after making eight or ten forced respirations to clear the lungs, until the mouth and nostrils had been closed more than a minute and a half; and that he continued to hold breath to the end of the second minute. A knowledge of this fact may in many cases be of great importance, as it may enable a diver to remain under water at least twice as long as he otherwise could do. It is suggested that possibly the exertion of swimming may have the effect of occasioning the lungs to be cleared; so that persons accustomed to diving may unconsciously avail themselves of this preparatory measure.

Another important fact, related in the same work, indicates the advantage of breathing condensed air, and thereby obtaining a larger supply of oxygen in the same bulk than with air of the ordinary pressure. After one of the disastrous occurrences at the works of the Thames Tunnel, Mr. Brunel, the engineer, descended in a diving-bell to examine the breach made by the irruption of the river into the tunnel. The bell descended to the mouth of the opening, a depth of about thirty feet; but the breach was too narrow to allow it to go lower, in order that the shield and other works, which lay eight or ten feet deeper, might be examined from the bell. Brunel therefore took hold of a rope, and dived below the bell for the purpose. After he had remained under water about two minutes, his companion in the bell became alarmed, and gave a signal which occasioned Brunel to rise. On doing so he was surprised to find how much time had elapsed; and, on repeating the experiment, he ascertained that he could with ease remain fully two minutes under water; a circumstance accounted for by the condensation of the air in the bell, from which his lungs were supplied, by the pressure of a column of water nearly thirty feet high, which would condense the air into little more than one half of its usual bulk.

Many plans were suggested for enabling persons to remain for a longer period under water than is possible by the natural powers of the body, long before extensive use was made of any of them. Beckmann alludes to a passage of Aristotle (problem xxxii., § 5), which has been supposed to intimate that in his time divers used a kind of kettle to enable them to continue longer under water; but this passage is variously rendered by different translators, and Beckmann appears to place little reliance upon it. He states that the oldest information we have respecting the use of the diving-bell in Europe is that of John Taisnier, quoted by P. Gaspar Schott. It occurs in the 'Technica Curiosa, sive Mirabilia Artis,' &c., of Schott, which was published at Nürnberg, in 1664, lib. vi., cap. ix., p. 393, and is taken from the 'Opusculum de Motu Celerrimo' of Taisnier, who says, "Were the ignorant vulgar told that one could descend to the bottom of the Rhine, in the midst of the water, without wetting one's clothes or any part of one's body, and even carry a lighted candle to the bottom of the water, they would consider it as altogether ridiculous and impossible. This, however, I saw done at Toledo in Spain, in the year 1538, before the emperor Charles V. and almost ten thousand spectators. The experiment was made by two Greeks, who, taking a very large kettle suspended by ropes with the mouth downwards, fixed beams and planks in the middle of its concavity, upon which they placed themselves, together with a candle. The kettle was equipoised by means of lead fixed round its mouth, so that when let down towards the water no part of its circumference should touch the water sooner than another, else the water might easily have overcome the air included in it, and have converted it into moist vapour."* Schott calls the machine described, "Cacabus aquaticus," or an "aquatic kettle;" but he also describes an apparatus called "Lorica aquatica," or "aquatic armour," which would enable those who were covered with it to walk under water, and which he seems to prefer to the "cacabus aquaticus" previously described.† This apparatus is represented in plate 31 of Schott's work, which shows a man walking into the water with a covering like a small diving-bell over his head, descending nearly to his feet.

In England, without noticing the supposed contrivance of a diving-machine by Roger Bacon, it is evident that the diving-bell was known at an early period. It is mentioned by Lord Bacon ('Novum Organum,' lib. ii. § 50; and 'Phænomena Universi,' p. 702) as a machine used to assist persons labouring under water upon wrecks, by affording a reservoir of air to which they might resort whenever they required to take breath.

Some curious information on submarine operations is given in the postscript to a little volume published at Edinburgh, in 1688, by George Sinclar, "sometime Professor of Philosophy in the College of Glasgow," entitled 'The Principles of Astronomy and Navigation.' The postscript contains an account of how "to buoy up a ship of any burden, from the ground of the sea," and states that among those who had, in this nation, attempted to recover property from wrecks by diving, was the late Marquis of Argyle, "who having obtained a patent from the king, of one of the Spanish Armada, which was sunk in the Isle of Mull, anno 1588, employed James Colquhoun, of Glasgow, a man of singular knowledge and skill in all mechanical arts and sciences." "This man," he proceeds, "not knowing the diving-bell, went down several times, the air from above being communicated to his lungs by a long pipe of leather. He only viewed and surveyed the ship, but I suppose buoyed nothing up." Sinclar subsequently states that about 1664, the (then) late Lord Argyle employed an ingenious gentleman, the laird of Melgim, who went down with a diving-bell and got up three guns. A third and more successful trial was made, he says, several years after; and, still later, one Captain Smith was so confident of obtaining the gold supposed to be lost with the ship, that he would not admit a co-partner in the enterprise; which, however, came to nothing. Sinclar proposed to raise wrecks by the buoyancy of arks or boxes, open at the bottom, which were to be sunk full of water, and then filled with air either by sending down casks of air; by bellows and a long tube; or otherwise. He alludes to the occasional use of casks for the purpose of raising vessels, and explains why, when at a great depth, they are liable to be crushed by the pressure of the water, showing that, by allowing the water to enter by a hole in the lower part of the cask, it would so compress the air as to produce an equilibrium of pressure, and thereby preserve it from fracture. About the time that the work above quoted was published, William Phips, who subsequently became governor of New England, attempted to raise treasure from the wreck of a Spanish ship sunk on the coast of Hispaniola. What was the precise character of his apparatus, we are not informed. His earliest experiments failed, but he was so confident of success, that he sought for assistance to enable him to prosecute his scheme. He at length obtained the patronage of the Duke of Albemarle, son of the celebrated Monk, and in 1687, after many difficulties, he succeeded in raising a large quantity of treasure, with which he returned to England; where he was honoured with knighthood for his enterprise. Most accounts state that the property he recovered amounted to 200,000*l.*; but in the 'Life of Sir William Phips,' published anonymously in 1697, but attributed to Increase Mather, it is stated as 300,000*l.* It is unnecessary to cite further instances of the use of diving apparatus, or to notice other early authors who have mentioned the diving-bell, except to observe that Beckmann alludes to engravings in editions of Vegetius on the art of war, published in 1511 and 1532, representing a diver with a cap, from which rises a long leathern pipe, terminating in an opening which floats upon the surface of the water; and to a figure published in a work on fortification, by Lorini, in 1607, which nearly resembles the modern diving-bell. Beckmann considers the insertion of the former as a proof that the person who drew them was not acquainted with the diving-bell, which he would otherwise have delineated. The machine described by Lorini consists of "a square box bound round with iron, which is furnished with windows, and has a stool affixed to it for the diver." Lorini, who was an Italian, does not lay claim to the invention of this apparatus.

---

* We quote from the translation in the English edition of Beckmann's 'History of Inventions,' by William Johnstone, second edition, 1814, vol. i., p. 184.

† His words are: "Longe melior est alia illa, quam ex Francisco Köslero proponit *Daniel Schwenterus* in Deliciis Mathematicis," Part 12, prop. 15.

Dr. Halley, in No. 349 of the 'Philosophical Transactions,' (vol. xxix.) describes the defects of the diving-bell, as previously used, and suggests a remedy for them. This paper alone would be sufficient, although it does not enter into the early history of the machine, to contradict the erroneous statement which has been made to the effect that Halley was the inventor of the diving-bell.

In its simplest form the diving-bell is a strong heavy vessel of wood or metal, made perfectly air and water tight at the top and sides, but open at the bottom. If such a vessel be gradually lowered into the water, in a perfectly horizontal position, the air which it contains cannot escape, and therefore the vessel cannot become full of water. This may be readily illustrated by plunging a glass tumbler, in an inverted position, into a vessel of water, and placing a bit of cork, or any other substance which will float, on the surface of the water, under the glass. If a bit of burning matter be laid upon the cork-float, it will be seen that it continues burning, although the glass and all that it contains be plunged far beneath the water; thereby proving that the upper part of the cavity of the glass is occupied by air, and not by water. In this experiment, however, it will be observed that the water does fill a small part of the cavity of the glass, and that it rises more into it when it is plunged to a considerable depth than when the rim is only just immersed beneath the surface. This is occasioned by the condensation of the air contained in the glass, which being very elastic and compressible, is condensed into a smaller space by the pressure of the superincumbent water, when the glass is plunged to a considerable depth, than it will occupy under the ordinary pressure of the atmosphere. Where the diving-bell is used for descending to a very small depth, as the pressure of the water is small, it will not rise in the bell to a sufficient height to be inconvenient; but at the depth of 33 feet the pressure is so great as to compress the air into one-half its original volume, so that the bell will become half full of water; and at a greater depth the air will be still more compressed, and the water will rise proportionately higher in the bell. This condensation of the air does not materially interfere with respiration, provided the descent of the bell be very gradual, as the air then insinuates itself into the cavities of the body and balances the pressure from without. The principal effect of the increased pressure is a pain in the ears, occasioned by the circumstance that the Eustachian tube does not allow the condensed air immediately to find its way into the cavities of the ear, so that the pressure on the outside of the tympanum is, for a time, unbalanced by a corresponding pressure from within, and occasions a sensation like that of having quills forced into the ears. This continues until the pressure of the air in the mouth, which at first has a tendency to keep the aperture of the Eustachian tube closed, forces it open; an action which is accompanied by a noise like a slight explosion. The condensed air then enters the interior cavities of the ear, and, by restoring the equilibrium of pressure on each side of the tympanum, removes the pain: which will return, and be remedied in the same manner, if the bell should descend to a greater depth. But while the mere condensation of the air in the bell does not render it unfit for respiration, it would soon become so if no means were provided for renewing it from time to time, as it becomes vitiated by repeated respiration. The improvements invented by Dr. Halley provided a remedy for this inconvenience, and for that of the contracted space left free from water, when, by being at a great depth, the air is compressed into a small volume, by affording a convenient means of supplying the bell with any required quantity of fresh air, without raising it to the surface.

The bell used by Dr. Halley was of wood, in the form of a truncated cone, 5 feet in diameter at the bottom, and three feet at the top, and containing about sixty cubic feet. This was coated with lead, and so weighted about the lower part that it would sink while empty, and would always remain in its proper position; that is, with the large open end downwards, with its rim parallel with the horizon. In the top of the bell was a very strong glass window, and a cock, by opening which the foul air might be allowed to escape. About a yard below the mouth of the bell was suspended a stage, so weighted that it might hang steadily. The whole apparatus was suspended from a sprit attached to the mast of a ship, and provided with tackle by which the bell might be raised or lowered, and the sprit might be slung round so as either to carry the bell over the hull of the vessel, or to suspend it clear of her side. The apparatus for conveying air to the diving-bell consisted of two barrels, holding thirty-six gallons each, weighted with lead to make them sink readily. Each of these had an open bung-hole in the lower end, to allow water to enter during their descent, so as to condense the air in the manner described when explaining the principles of the diving-bell itself. There was also a hole in the upper end of each, to which was fitted an air-tight leathern hose, long enough to fall below the bottom of the barrel, and having its loose end so weighted that it would fall naturally into that position. These air-barrels were attached to tackle, by which, with the easy labour of two men, they might be made to rise and fall alternately, like two buckets in a well; and, by lines attached to the lower edge of the bell, they were so guided in their descent that the mouth of the hose always came directly to the hand of a man who stood upon the stage suspended from it. As the apertures of the hose were, during their descent, always below the level of the barrels, no air could escape from them; but when they were turned up by the attendant, so as to be above the level of the water in the barrels, the air rushed out with great force into the bell, the barrels becoming at the same time full of water. By sending down these air-barrels in rapid succession, the air in the barrel was kept in so pure a state that five persons remained in the bell, at a depth of nine or ten fathoms, for more than an hour and a half at a time, without injurious consequences; and Halley states that he could have remained there as long as he pleased, for anything that appeared to the contrary. In addition to this, by the copious supply of air admitted during the descent, the bell was kept constantly full of air, and the water was prevented from entering to any inconvenient extent. Halley observed that it was necessary to be let down gradually at first, and to pause at the depth of about twelve feet, to drive out, by the admission of a supply of air, the water which had entered the bell. When the diving-bell was arrived at the required depth, he let out, by the cock in the top of the bell, a quantity of hot impure air, equal to the quantity of fresh air admitted from the barrels. This foul air rushed up from the valve with such force as to cover the surface of the sea with a white foam. So perfect was the action of this apparatus, that Halley says he could, by removing the hanging stage, lay the bottom of the sea so far dry, within the circuit of the bell, as not to be over shoes thereon. When the sea was clear, and especially when the sun shone, sufficient light was transmitted to allow a person in the bell to write or read; and when the sea was troubled and thick, which occasioned the bell to be as dark as night, a candle was burnt in it. Halley sometimes sent up orders with the empty air-barrels, writing them with an iron pen on plates of lead. Having, by these ingenious contrivances, removed the principal difficulties attending the use of the diving-bell, Halley foresaw its extensive utility. He observes, "This I take to be an invention applicable to various uses, such as fishing for pearl, diving for coral, sponges, and the like, in far greater depths than has hitherto been thought possible. Also for the fitting and plaining of the foundations of moles, bridges, &c., upon rocky bottoms; and for the cleaning and scrubbing of ships' bottoms when foul, in calm weather at sea." "But," he adds, "as I have no experience of these matters, I leave them to those that please to try." To several of these purposes the diving-bell has, since the date of this paper (1717), been applied with great advantage.

In 1732 a communication was made to the 'Philosophical Transactions,' No. 444, vol. xxxix., p. 377, by Martin Triewald, "Captain of Mechanics, and military architect to his Swedish majesty," respecting an improvement of the diving-bell. He had the sole privilege of diving upon the coasts of the Baltic belonging to the king of Sweden; and he expresses his opinion, founded on much experience, that no apparatus but that on the principle of the "campana urinatoria," or diving-bell, could be safely used at great depths. His letter mentions a man, then sixty-three years old, who had followed the business of diving with the common diving-bell ever since he was twenty. Triewald's diving-bell was of copper, tinned inside, smaller than that of Dr. Halley, and managed by two men. A stage for the diver to stand upon was suspended at such a depth below it, that the man's head would be but little above the level of the water, where the air is cooler and fitter for respiration than in the upper part of the bell; and a spiral tube was attached to the inside of the bell, with a wide aperture at the bottom, and a flexible tube and mouth-piece at the top, so that, when the diver was up in the bell, he might inhale cool air from the lower part, exhaling the foul air by his nostrils. Dr. Halley's air-barrels are applicable to a bell of this construction. In lieu of windows of flat glass, Triewald used convex lenses to admit light to the bell.

In 1775 Mr. Spalding, of Edinburgh (who, according to the 'Annual Register,' vol. xix., p. 202, was a grocer), having some concern in a vessel which had been lost on the Fern Islands, was induced to make some experiments with Dr. Halley's diving-bell, with a view to recovering property from wrecks, and was thereby led to the invention of means for rendering it more safe and manageable. For these inventions he received, in 1776, a reward of twenty guineas from the Society for the Encouragement of Arts, Manufactures, and Commerce, in the first volume of whose 'Transactions' (pp. 220-238) they are fully described. Mr. Spalding's communication contains also a very interesting account of his experiments with Halley's diving-bell. The improved diving-bell contrived by Mr. Spalding was made so light, that, with the divers and the weights attached to the rim, it would not sink; the weight necessary to counteract its buoyancy being added in the form of a large balance-weight, suspended from its centre by a long rope, which was so mounted on pulleys that the divers could either draw the balance-weight up to the mouth of the bell or allow it to fall to a considerable depth below it. Thus, by letting the weight down to the bottom, the divers could, as it were, anchor the bell at any required level; or prevent its further descent if they perceived a rock or part of a wreck beneath it, which might otherwise overturn it.

Also, by hauling in the rope while the weight was at the bottom, the persons in the bell might lower themselves at pleasure. Another improvement consisted in the addition of a horizontal partition near the top of the bell, which divided off a chamber that might, by suitable openings and valves, be filled either with water, or with air from the lower part of the bell; so as to alter the specific gravity of the whole machine, and thereby to cause it to ascend or descend at pleasure. The bell was supplied with air by an apparatus resembling that of Dr. Halley; and ropes, stretched across the bell, were used instead of seats and platforms for standing on. By these arrangements the persons in the diving-bell were enabled, in case of accident, to raise themselves to the surface without any assistance from above; and it was rendered so perfectly manageable, that it might be removed to a considerable distance from the point at which it descended; its outward motion, and its return to the vessel for the purpose of being hauled up, being assisted by a longboat, which carried the signal-lines and the tackle for working the air-barrels.

Though not in chronological order, it may be well here to allude to an improvement upon Spalding's apparatus, contrived by Mr. John Farey, junior, and described by him in the article 'Diving-Bell,' in Brewster's 'Edinburgh Encyclopædia.' He proposes to make the upper chamber of the diving-bell very strong and air-tight, without any openings for the admission of water. In the partition are fixed two forcing-pumps, by which a portion of air should be forced into the upper chamber, whenever, during a pause in the descent, the lower chamber, or the cavity of the bell, is replenished with air. By this means the upper chamber is made a reservoir of condensed air, from which the bell may be replenished with air when it is desired to increase its buoyancy by forcing out the water from the lower part. In like manner, the buoyancy of the bell can be at any time diminished by pumping some of the air from it into the upper chamber, whereby the water will be allowed to enter to a greater height; and, as this is effected without wasting the air, there is no danger of diminishing the buoyancy of the machine to a degree which would prevent it from rising in case the suspending rope or chain should break. Mr. Farey recommends the form of the frustum of an elliptic cone, for diving-bells intended for descending to wrecks; the dimensions being, for a bell to hold two persons, 6 feet by 4 at the base, 3 feet 6 inches by 2 feet 6 inches at the top, and 6 feet 6 inches high. He also suggests the use of a pressure-gauge in the bell, to show the divers what depth they have descended to; and of a compass to enable them to ascertain and give proper signals respecting the direction in which the bell should be moved. These signals are given by snatching a rope, which may be marked in the same manner as a deep-sea lead-line [SOUNDINGS], so that, after giving a signal to raise or lower the bell, the diver may, by hauling in a certain quantity of the signal-line, intimate the height to which the bell should be moved. Farey recommends that the men be attached by ropes to the bell, so that in case of falling, they may not sink; and that, in case of being obliged to leave a wreck to which it is intended again to dive, the balance-weight may be left at the bottom, with a buoy attached to the upper end of its rope, so that the right point for descending may be found without difficulty.

The credit of having been the first to apply the diving-bell in aid of civil engineering operations is usually attributed to Smeaton, who used it in 1779 in repairing the foundations of Hexham Bridge. The Report in which he recommended its adoption is a very interesting document, as it affords a familiar explanation of the principle of the diving-bell. It is dated September 16, 1778; and is printed in the collected edition of his 'Reports,' vol. iii., p. 279. The bell used on this occasion was an oblong box of wood, 4 feet high, 2 wide, and 3½ long; and it was supplied with air by a pump fixed on the top. The river being shallow, the bell was not covered with water; but in 1788 the diving-bell was used in a much more important work, Ramsgate harbour, by the same engineer. Being here used at a considerable depth, an apparatus was employed for forcing in a supply of air through a flexible pipe, by means of a forcing-pump in a boat. The bell used in this work was of cast-iron, similar in form to that employed at Hexham, but 4½ feet high, 4½ long, and 3 wide. Its weight was fifty cwt., and the thickness was so adjusted that it would, without the addition of any weights, sink in the proper position. In levelling foundations under water by this machine, the surface of the water at the bottom of the bell formed a convenient and unerring level to work to; and in this, as well as in the subsequent operation of building, every necessary motion was given to the bell by the tackle by which it was suspended; signals being made from below by striking one, two, three, or more blows upon the side of the bell with a hammer.

Since the time of Smeaton the diving-bell has been frequently, and with great advantage, employed in submarine works; sometimes in situations in which it would have been impossible to construct a coffer-dam, or to perform the required operations by any other means. The diving-bells used in such works are usually formed on the model of that made for the works at Ramsgate harbour; but the mode of suspension differs according to circumstances. The bell may be suspended over the side or end of a vessel; through an opening in the centre of a barge; from frame-work resting upon two barges, placed parallel with each other, but at such a distance apart as to allow the bell to descend between them, or from a scaffolding supported by piles. In operations at the harbour of Howth, near Dublin, the late Mr. Rennie used a diving-bell suspended from a kind of railway scaffolding like that described under SCAFFOLDING, as used in erecting large stone buildings; two carriages being used upon the scaffold, one to lower the stones, and the other to manage the bell. By the apparatus described as above, aided by ropes attached to the stones, and managed by the men in the bell, the submarine masonry could be executed with great facility. Of the use of this important machine in recovering property from wrecks, the operations upon that of the Royal George afford a familiar example. According to the 'Annual Register,' vol. lix., p. 42, this wreck was first surveyed by the diving-bell on the 24th of May, 1817. Smeaton's method of supplying air to the bell is that most commonly employed; but that of Halley may, in some cases, have the advantage.

The diving-bell, with some slight modifications in the details of the pumps, and of the hoisting and lowering apparatus, continues to be used in the execution of hydraulic masonry of a difficult and delicate nature; and occasionally, as in the execution of the harbour of refuge of Dover, for the purpose of raising the huge masses of masonry in the jetties carried out into deep water.

In whatever way a diving-bell may be mounted, it is essential that it should descend very gradually, and that its descent should be perfectly under control. In 1838, Mr. Richard Jones, who had been placed in a very perilous situation by the failure of the crab by which a diving-bell in which he was descending was being lowered, was rewarded by the Society of Arts for a contrivance to prevent the occurrence of such an accident. His improved crab has a brake, regulated by the centrifugal motion of two balls, like the governor of a steam-engine; so that, while the crab revolves slowly, and therefore allows the bell to descend gradually, the brake may not be called into action; but if it should, from any cause, be overpowered by the weight of the bell, so as to run down with dangerous velocity, the separation of the balls should disengage the brake, and thereby stop the motion of the crab. The machine is described and represented in detail in vol. lii., p. 72, &c. of the Society's 'Transactions.'

Of late years a system, originally suggested by Coulomb in 1788, of executing masonry, or other hydraulic works, at great depths from the surface, has been used with considerable success at the Rochester and the Saltash bridges. In these cases the foundations were laid without coffer-dams, by means of air-tight chambers in which the workmen laboured in an atmosphere of condensed air. An account of the machinery used at Rochester bridge was printed by Mr. Hughes, who conducted the works; and a description of an analogous operation executed at Croissac, in France, has been given by M. de la Gournerie in the 'Annales des Ponts et Chaussées' for 1848. The cylinders used by Dr. Potts have a distant connection with this class of operations, but it will be more convenient to notice the whole subject more in detail under the article FOUNDATION.

Many plans have been proposed for enabling a man to walk beneath the surface of water, or to dive in such a manner as to assist in the raising of anchors, or the recovery of property from wrecks, by means of waterproof coverings for the head and upper part of the body, or of strong vessels in which every part but the arms should be encased; a supply of air being either transmitted from above by a flexible pipe, or contained in the cavities of the protecting armour. Such apparatus may be conveniently used at small depths; but at any considerable depth they are both dangerous and inconvenient, because the strength necessary to enable them to bear the pressure of the water is incompatible with the flexibility essential to the free use of the limbs. Dr. Halley alludes, in his paper on the diving-bell, to some contrivances of this kind; and in a subsequent paper ('Phil. Trans.,' No. 368, vol. xxxi., p. 177) he describes an apparatus of his own invention, by which a man might leave the diving-bell, and walk about at the bottom of the sea; his head being covered by a heavy leaden cap like a small diving-bell, supplied with air by a flexible tube extending from the large bell. The diver was to coil this tube round his arm, and unwind it as he left the bell, and to use it as a clue to direct him to the bell in returning. This pipe was formed of leather soaked in oil and hot wax, and was held open by a spiral coil of brass wire, its internal diameter being about one-sixth of an inch. The pipe was then covered with several thicknesses of gut, and over all with leather. The modern invention of waterproof India-rubber cloth, which has been applied in various ways to diving apparatus, affords great facilities for the manufacture of water-tight tubes for such a purpose. So long as the helmet was above the level of the water in the bell, it would be kept full of air; and in case of having to stoop below that level, as in getting out of or into the bell, the diver had only to close a valve, by which the air in the helmet was prevented from returning into the bell. The front of the helmet was glazed; and the diver, who was clothed in a thick woollen dress, fitting close to the body, to diminish the effect of the coldness of the water, was enabled to walk by means of a weighted girdle and weighted clogs. Aquatic armour, whether supplied with air from above, or carrying a store in its cavities sufficient to last for the time the diver intends to remain submerged, has been brought so little into use that it is needless to devote the space required for a minute description. The apparatus of M. Klingert, which was first described in a pamphlet published at Breslau in 1798, has been fully explained in Tilloch's 'Philosophical Magazine' (vol. iii., pp. 59 and 171), and in many other English works; and a more recent contrivance of similar character has been exhibited at the Polytechnic Institution, London. In the 'Gentleman's Magazine' for September, 1749 (vol. xix., p. 412), will be found a notice of a curious diving apparatus, consisting of a case inclosing the person, with the arms protruding in flexible sleeves, which is stated to have been contrived and used for many years by a person named John Lethbridge, who writes from Newton Abbot, near Exon, Devon, and states that he tried experiments as early as 1715. This was supplied with air by flexible pipes. A similar machine was contrived by Mr. Rowe in 1753, which was to be lowered by tackle like a diving-bell.

One of the diving-machines contrived by Klingert was so arranged that it would rise or fall by the motion of a piston in a cylinder, in the lower part of the apparatus, by which the diver could vary the density of the air, and consequently the specific gravity of the machine, at pleasure. A very simple apparatus for enabling a person diving without a bell, or any of the machines above noticed, to effect the same object, has been recently invented by Mr. W. H. Thornthwaite of Hoxton. It is described in the fifty-second volume (p. 243) of the 'Transactions' of the Society of Arts, by whom Mr. Thornthwaite was rewarded for it in 1839. It consists of a hollow belt of India-rubber cloth, to which is attached a small but strong copper vessel. Into this vessel air is to be forced by a condensing syringe, until it has a pressure of thirty or forty atmospheres. The belt is then put on, in a collapsed state, so that it affords no buoyancy, and does not impede the descent of the diver; but when he desires to rise, he opens a valve, by which the condensed air escapes from the copper vessel into the belt. As it expands the belt, it affords sufficient buoyancy to raise the diver immediately to the surface.

An account of schemes for submarine descent would hardly be complete without some allusion to projects for submarine navigation, of which many have been suggested. An early instance is that of Cornelius Drebell, or Drebelle, who is said to have made a vessel to be rowed under water, which was tried in the Thames by order of James I., and carried twelve rowers, besides passengers. This vessel is alluded to by Robert Boyle, in his 'New Experiments Physico-Mechanicall, touching the Spring of the Air, and its effects,' &c., published at Oxford in 1660. Pages 363-5 of this curious work contain an account of Drebell's experiment, and state that he accounted his chief secret to be "the composition of a liquid that would speedily restore to the troubled air such a proportion of vital parts as would make it again, for a good while, fit for respiration." The composition of this liquid for enabling the same air to be used again and again, was never made public. Bishop Wilkins, who also favoured some other whimsical projects, devoted a whole chapter of his 'Mathematicall Magick,' which was published in 1648, to a dissertation 'Concerning the possibility of framing an Ark for Submarine Navigation.' In this work (book ii., chap. 5) he recites the difficulties of the scheme, but evidently considers them not insurmountable; and afterwards he enlarges upon its advantages, in privacy, security from pirates, storms, ice, &c., in naval warfare, philosophical experiments, discoveries, &c., and at length states that "All kind of arts and manufactures may be exercised in this vessel. The observations made by it may bee both written and (if need were) printed here likewise. Severall Colonies may thus inhabit, having their children born and bred up without the knowledge of land, who could not chuse but be amazed with strange conceits upon the discovery of this upper world." The bishop adds, "I am not able to judge what other advantages there may be suggested, or whether experiment would fully answer to these notionall conjectures." In 1774 a projector named Day lost his life in an experimental descent in Plymouth Sound, with a vessel of about 50 tons burden, which he thought he could have caused to rise after a lapse of several hours; and this experiment, of which an account is given in the seventeenth volume of the 'Annual Register' (p. 245), led to the publication, in the following year, of a 'Philosophical Dissertation on the Diving Vessel projected by Mr. Day, and sunk in Plymouth Sound,' by N. D. Falck, M.D., which contains a representation and minute description of the vessel, an account of the ineffectual attempts to raise her, and much other curious matter. One of the most successful machines contrived for submarine navigation was that of Mr. Bushnell of Connecticut, which was projected in 1771, and completed in 1775. Bushnell's chief object appears to have been the introduction of submarine warfare. His vessel, which was propelled by screws, somewhat resembling those now in use for steam-vessels, is described in the 'Transactions of the American Philosophical Society,' vol. iv., p. 303, whence the account was copied into 'Nicholson's Journal,' vol. iv., p. 229. The subsequent projects of Fulton for the same purpose have been referred to elsewhere. [FULTON, ROBERT, in BIOG. DIV.] In the article 'Diving-Bell,' in the 'Encyclopædia Metropolitana,' written by Mr. Babbage, a detailed plan is laid down for the construction of a vessel for submarine navigation. Among the suggestions there made are those of using oxygen, condensed in store-vessels, to replenish the air, and of absorbing the carbonic acid produced by respiration, either by cream of lime, or by a strong solution of ammonia.

DIVINING ROD, a forked branch, usually of hazel, by which it has been pretended that minerals and water may be discovered in the earth. The rod, if slowly carried along in suspension, dips and points downward, it is affirmed, when brought over the spot where the concealed mine or spring is situated. Other mysterious powers—such as those of discovering the lost boundaries of lands, identifying murderers, discovering hidden treasure, and even of detecting the birth-place and parentage of foundlings—have also been attributed to the divining rod. The rod is sometimes called the Virgula Divina, or the Baculus Divinatorius, or the rod of Aaron, or the Caduceus (after the wand of Mercury). Many persons with some pretensions to science have been believers in the powers ascribed to the divining rod. George Agricola, the able and learned German metallurgist of the 16th century, and in later times John Sperlingius and Theodore Kirchmaierus, who have both written *Disputatiunculæ* on the rod, all say the devil is in it. In 1690 appeared an account of a mason in Dauphiné, "who, guided by a hazel rod, followed a murderer for forty-five hours over land, and thirty hours on the water." Richelet, in his Dictionary (art. 'Baguette Divinatoire'), confesses that after what he has seen he cannot entertain any doubt as to its possessing the wonderful qualities ascribed to it. The learned Morhoff, who was eminent for his scientific as well as literary knowledge, admits that it is not clear to him whether the effects be natural or the result of demoniac agency. M. Thouvenot published at Paris, in 1781, a 'Memoir on the relation of the phenomena of the Divining Rod to those of Electricity and Magnetism;' and Pryce, in his 'Mineralogia Cornubiensis' (fol. 1778), has collected accounts of numerous successful experiments which he says were performed by the instrument. Some remarks on the rod and on the attempts that have been made to explain its fancied operation, may be found in the Marquis le Gendre's 'Traité de l'Opinion;' and there is a discussion of the subject, which is well worth reading, both for the reflections and some curious facts which it contains, in Bayle's 'Dictionary,' in the notes to the article 'Abaris.'

The present century has not been without its contributions, favourable and unfavourable, to the pretensions of diviners. Dr. Hutton, in 1803, in his edition of 'Ozanam's Recreations,' ridiculed the whole subject of divination. Lady Noel, mother of Lord Byron, hearing of this work, wrote to inform Hutton that she herself possessed this disputed power; that she had been induced to try by observing the success of a peasant in Provence; that, in company with Mr. Dawson Turner, at Warlingham, she had made a trial; that the hazel twig *did* turn when she came over a hidden stream of water; and that, so far from using any muscular force to make the rod turn, "her thumbs and fingers became quite reddened and sore from the efforts she made to keep it from turning." Thus challenged, Hutton invited her to Woolwich, where, according to the accounts of others (but not, we believe, of the learned mathematician himself) a hidden spring of water was pointed out by the divining rod. Dr. Herbert Mayo, in a series of articles published in 'Blackwood's Magazine,' in 1847, on the Truths contained in Popular Superstitions, and afterwards collected into a volume, placed some credence in the divining rod. He states it as a popular belief in Cornwall, that about one person in forty possesses the faculty of discovering the locality of veins of copper and tin by means of the rod. They proceed thus: A hazel twig is cut just below where it forks; it is stripped of its leaves; and then each branch is cut to about a foot in length, leaving a stump three inches long. The hazel fork thus prepared is to be held by the branches, one in each hand, the stump or point projecting forwards; the arms of the dowser or diviner hang by his sides, but the elbows being bent at a right angle, the forearms are advanced horizontally. The hands are held eight or ten inches apart, the knuckles down, and the thumbs outwards; the ends of the branches appear between the roots of the thumbs and fore-fingers. The experimenter walks over the ground in the full expectation that, if he possess the mystic gift, as soon as he passes over a vein of metal, or an underground spring, the fork will begin to move spontaneously in his hand, rising or falling as the case may be. When at Nassau, about the time of the publication of his papers, Dr. Mayo made many experiments by the aid of a young man named Edward Seebold, and two of his brothers, together with two other persons; these persons walked many times to and fro, on a piece of ground known to contain water beneath, holding prepared twigs of hazel in their hands; the hazel twigs made many circular and vibratory movements, apparently involuntarily on the part of the experimenters; but Mayo failed to draw any very definite conclusions on the matter: and in a later edition of his work, in 1851, he stated that Seebold seemed to have lost the power altogether. Mr. Phippen, in a pamphlet published in 1853, contends for the practicability of discovering water, metals, and coal by the divining rod. It appears that, being on a visit to his brother, a surgeon at Wedmore, in Somersetshire, the two were induced to test the powers of two dowsers or professional diviners, named Mapstone and Adams. Mapstone thereupon discovered a hidden spring of water, at a place where a farmer named Edwards was very anxious to sink a well. Adams also had the reputation of having dowsed successfully for more than a hundred wells, discovering not only water but metal, the existence of which underground had not been previously known to him. When these statements were made public in two of the London newspapers, Mr. Marshall, one of the partners in the great flax factory at Leeds, wrote to ask Mr. Phippen whether the facts had been correctly reported, and whether Adams would try his reputed skill in Yorkshire? A meeting was arranged; and Mr. Phippen prints in his pamphlet Mr. Marshall's account of what took place. The dowser certainly did succeed in naming, with a great approach to correctness, the exact locality of many springs underneath the ground; he being previously blindfolded, and led about in various directions. The power, whatever it might be, was not confined to a mere spot of water, but extended, it is stated, to a line or hidden watercourse. Adams, it is asserted, found that copper and iron wire succeeded with him nearly as well as a hazel twig.

Scientific men, almost without exception, regard the asserted power as a fraud or a delusion. Devonshire and Cornwall people stoutly assert its reality. M. Chevreul, in an essay published in 1854, 'De la Baguette Divinatoire, du Pendule dit Explorateur, et des Tables Tournantes, au point de vue de l'Histoire, de la Critique, et de la Méthode Expérimentale,' classes the divining rod with table-turning, as being the performances of persons who deceive themselves, but do not knowingly or wilfully deceive others. If we look at the old practice of divination by Bible and Key, we should probably see that all rest on the same basis. Supposing property to have been stolen, a key was placed in a Bible, at the 1st chapter of Ruth, or the 19th of Proverbs, or the 50th Psalm; the main body of the key was tied tightly in the book, and the projecting loop or handle was hung loosely on a finger; the experimenter repeated the names of suspected persons, together with portions of the said chapters; and when the real thief was named, the key was said to fall off the finger. In Eusebe de Salle's 'Peregrinations en Orient,' published in 1840, the author describes a scene which he witnessed at the house of the English Consul at Aleppo, between an English lady and a Syrian Christian: a dispute arose whether she had received some jewellery from an Aleppo jeweller: she tried the Bible and Key test, and found it tell against herself; whereupon she left the room directly, made a search, and found the jewels in a drawer.

The subject has lately been a good deal discussed. The prevailing opinion among those who would dispassionately apply scientific tests, appears to be that the whole is an example of the phenomenon of *expectant attention*, or the effect of dominant impression on the mind, acting *unconsciously* upon and through the nerves and muscles.

DIVINITY. [THEOLOGY.]

DIVISIBILITY, DIVISOR. Any number or fraction admits of division by any other, in the extended arithmetical sense which considers *parts* of a time as well as times. Thus 12 contains 8 a time and half a time, or 12 divided by 8 gives 1½. The adjective *divisible* is nevertheless applied, not to any number as compared with any other, but only as compared with such numbers as are contained a whole number of times in the first. Thus 12 is said to be divisible by 6, and is said to be not divisible by 8. Or, both in arithmetic and algebra, divisible means "divisible without introducing fractions into the result."

The number of divisors which any number admits of is found as follows. Ascertain every prime number which will divide the given number, and how many successive times it will do so. Add one to each of these numbers of times, and multiply the results together. Thus, the number 360 is made by multiplying together 2, 2, 2, 3, 3, 5; or is divisible by 2 three times (3 + 1 = 4), by 3 twice (2 + 1 = 3), and by 5 once (1 + 1 = 2). And 4 × 3 × 2 = 24, the number of divisors which 360 admits of. But among the 24 divisors are included 1 and 360.

DIVISIBILITY OF MATTER. Every substance with which we are acquainted admits of being divided into parts, and each of these may be repeatedly subdivided. Indeed no limit has been assigned to this process of continual subdivision, although it is probable from chemical reasoning, that the ultimate elements of matter are indivisible and unalterable, whence they are called *atoms*. [ATOMIC THEORY.] We know nothing of the absolute size of these atoms, except that they cannot exceed certain magnitudes which may be calculated, but of their extreme minuteness we can form no correct idea. The following example from Tomlinson's 'Introduction to the Study of Natural Philosophy' will show how vain figures sometimes are to give adequate ideas of truth. It can be proved by geometrical reasoning, invented by Sir Isaac Newton, that "a film of soapy water will, if carefully protected from all disturbance, hold together until it has been reduced by draining to the thickness of less than a 2,600,000th of an inch. Pure water will not hold together in this way, but the admixture of less than the hundredth of its bulk of soap will confer this property on the whole of the water. Now, in order to produce this effect, it is evident that there must be a portion of soap (at least *one* atom) in every cubic 2,600,000th of an inch of the solution. But the soap, when dry, occupies less than 100th of the bulk of the solution. Therefore a single atom of soap, in the solid state, cannot possibly occupy so much as the hundredth of a cubic 2,600,000th of an inch; that is, not so much as a 1,757 trillionth (1,757,000,000,000,000,000,000th) of a cubic inch." In the same work an example is given in which Dr. Thomson, the chemist, shows that an atom of lead cannot weigh more than $\frac{1}{\text{[illegible]}}$th of a grain, while the atom of sulphur by which the lead is made visible cannot weigh more than $\frac{1}{2,015,000,000,000}$th of a grain.

Writers on natural philosophy are accustomed to excite the astonishment of their readers by details respecting the divisibility of gold, the enduring scent of musk, the minuteness of the blood discs, the attenuated but complicated structure of the spider's thread, the thousands of infusoria which might swim side by side through the eye of a needle, &c., but such details as these are of very little use except to prove what we already abundantly know, that matter is divisible, and that the limit of that divisibility has not been defined, even supposing the philosopher to have powers adequate to the definition.

DIVISION, the process of ascertaining how many times and parts of times one number is contained in another. The usual arithmetical rule consists in a continual approximation to the result required. We write underneath,—1, the common process; 2, that of which it is an abbreviation; 3, a short summary of the *rationale*.

```

The whole contains a number as often as all its parts put together contain that number: and 23 meaning 23,000, and 16 being the highest multiple of 8 below 23, then the 16,000, which is part of 23,000, contains 2000 eights, and it is left to be seen how often the remaining 7000, and the 475 (making 7475) contain 8. The 74 is 7400 and 9 times 8 being 72, the 7200 which is part of 7400, contains 900 eights, and it is left to be seen how often the remaining 200 with the 75 (making 275) contains 8. The 27 is 270, of which the part 240 contains 30 eights, and the remaining 30 together with the 5 (making 35) is left. Of this, 32 contains 4 eights, and the remaining 3 does not contain 8 so much as one time, but the eighth part of 3 units is three times the eighth part of a unit, or ⅜: whence the answer.

In finding how many times, or parts of times, one fraction is contained in another, the following principle is applied. If two numbers or fractions be multiplied by any number, the number of times, or parts of times, which the first contains the second, is not altered. Thus 7 contains 2 just as 14 contains 4, or as 21 contains 6, &c. If then we take two fractions, such as $\frac{3}{7}$ and $\frac{2}{11}$, it follows that $\frac{3}{7}$ contains $\frac{2}{11}$ just as 77 times $\frac{3}{7}$ contains 77 times $\frac{2}{11}$, or as 33 contains 14: that is, 2 times and $\frac{5}{14}$ of a time. This may easily be shown to give the common rule.

The division of one decimal fraction by another presents a difficulty, slight indeed, but quite sufficient to prevent most persons from becoming expert in the use of tables. The rules given are frequently incomplete, and always such as would render even a practised computer liable to mistake. The question is how to place the decimal point rightly in the result, and this may be best done a follows:—

1. Alter the dividend or divisor by annexing ciphers, until both have the same number of decimal places. This being done—

2. Annex as many ciphers to the dividend, or take away as many from the divisor (or partly one and partly the other) as there are to be decimal places in the result: then divide as in whole numbers, and mark off the given number of decimal places.

Example I.—Find out, to three decimal places, how often ·076 is contained in 32·1.

First step: ·076 and 32·100.
Second step: ·076 and 32·100000.
76)32100000(422368—rem. 32.
Answer. 422·368.

Example II.—Find out, to 7 decimal places, how often (what fraction of a time) 236·5 is contained in ·001.

First step: 236·500 and ·001.
Second step: 236·5 and ·00100000; namely, *two* ciphers struck off the divisor and *five* annexed to the dividend (making *seven*).

2365)100000(42—rem. 670.
Answer. ·0000042.

In making complicated divisions, it is much the shortest plan, and very much the safest, to begin by forming the first nine multiples of the divisor by continued addition (forming the tenth for proof).

DIVISION OF EMPLOYMENTS, in political economy, is an important agent in increasing the productiveness of labour. It is by labour alone that wealth is produced. It is a law of man's nature, that "by the sweat of his face he shall eat bread;" and in return for his labour he acquires various sources of enjoyment. The ingenuity with which he has been endowed, and the hard necessities of his condition, lead him to discover the most effective means of applying his labour to whatever objects he may be seeking to attain. He desires, first, to work no more than is necessary; and secondly, to obtain the largest return—the most abundant enjoyment, for his industry. He soon finds that his own unaided labour will scarcely provide for him the barest necessaries, and that ease or enjoyment is unattainable. Thus, instead of each man labouring separately and independently of all others, many men combine together for securing the various objects of life, by means of their joint labour; and this combination of labour leads to division of employments. Labour is naturally exerted in these two forms in the very earliest stages of society. The first pair whom God's ordinances and their own instinct united, must have combined for the support of themselves and their common family, and diversity of sex alone must have produced distinct employments. Among savages the man engages in the chace, for which he has a natural predilection, and for which his strength adapts him, while his mate rears their children and executes those functions which are suited to her sex, but which are as conducive to the comfort of both as if both performed them. In this manner a division of employments naturally arises, and each family affords an example of its origin and character.

This combination for a common object, succeeded by a division of employments, pervades every process of human industry, and increases in variety and complexity with the growth of civilisation. One of the earliest forms of industry is that of fishing, and none, perhaps, exemplifies more aptly the mode in which labour is necessarily applied to the purposes of life. A man desirous of building a fishing-boat may cut down a tree, without any assistance from others, and may even hew it into shape; but if it be larger than a mere canoe he cannot, by his own strength, remove it from the spot on which the tree had fallen, and launch it upon the sea. To effect this, others must combine their strength with his. To manage a boat the labour of more than one man is ordinarily required, and the larger the boat the greater must be the number who combine to navigate it. If they paddle or row it, their labour is simply combined for one purpose and in one manner, except that one, instead of rowing, may probably steer the boat. As the art of navigation improves and its objects become multiplied, in addition to a more extensive combination of men in pursuit of the same objects, a diversity of employments ensues. In a deep-sea fishery, some attend to the nets, others to the sails; and on their return to land, some arrange the nets to dry and repair them, while others are engaged in disposing of the fish.

From these illustrations it is evident that the cause of a division of employments is to be sought in the nature and circumstances of man. It is not the result of extraordinary foresight, but is suggested by the most common exigencies of life; its convenience is obvious, but the feeling which prompts men to adopt it is spontaneous and as it were intuitive. It is a social necessity, and the very foundation of any social system whatever, yet it is practised almost unconsciously by the greater part of mankind. Its existence, however, lies so open to observation that it is scarcely to be ranked as a discovery of political economy; but that science, having noted the facts of a combination of labour and a division of employments, explains their uses and results; and in pursuing these inquiries it develops some of the most important principles connected with the production and distribution of wealth. To these inquiries we must now devote our attention.

As labour is the lot of man, it is desirable that his labour should be as productive as possible, in order that the sum of his enjoyments should exceed that of his endurance. This result is attained by several men combining their labour for one object, and pursuing different employments for their reciprocal benefit, instead of each man labouring independently for himself and employing himself in the same manner as all other men. A division of employments, therefore, is not only a natural incident of labour, but is an important auxiliary of human enjoyment. The means by which it adds to the efficacy of labour are described by Adam Smith to be—1st, an "increase of dexterity in every particular workman;" 2ndly, "the saving of the time which is commonly lost in passing from one species of work to another;" and, 3rdly, "the invention of a great number of machines which facilitate and abridge labour, and enable one man to do the work of many:" to which may be added, 4thly, the separation which it causes between labour and the direction of labour; 5thly, the power which it gives of using machinery effectually, when invented; 6thly, the opportunities of exchange which it affords, and the means of availing ourselves of the enjoyments arising from the natural capabilities of the soil, climate, situation, or mineral productions of different parts of the world, and of the peculiar aptitude of their inhabitants for various kinds of industry.

1. The superior dexterity of workmen engaged exclusively in one occupation is universally known. "Use is second nature," and when a man has been long accustomed to a particular employment, not only has he acquired great dexterity, but his mind appears to be endowed with faculties specially adapted to his business. The jockey seems to have been born for the saddle; the sailor for the ship: both are active, intelligent, dexterous; but fancy their occupations exchanged or combined! the sailor in the saddle, the jockey at the helm; or both alternately riding the favourite horse at Newmarket and furling the topgallants of a three-decker at Spithead! The constant exercise of the faculties in any art or business gives them an aptitude for it, which to others is a matter of astonishment. The eye and the hand perform their offices with such precision and rapidity, that their work seems spontaneous, as it were, and independent of the will of the workman. Without deliberation, almost without care, the business is done; and done better than others could do it with the greatest pains. All processes of art and manufacture, and the daily experience of all men, confirm this statement as an unquestionable fact. (Babbage, 'Economy of Machinery and Manufactures.') The advantages of peculiar skill are that men can work better and faster, that the products of their labour are more valuable and more abundant, and that their contributions to the general stock of the world's enjoyments are multiplied. By following out these advantages through all their relations, they will be found to be the primary source of wealth; and, in a moral point of view, the main cause of social progress and of the development of the highest faculties of man.

2. "The saving of time which is commonly lost in passing from one species of work to another" enables a man who is constantly engaged in one process to perform more work than he would have been able to get through in the course of a day, if he had been required to change his employment. For this reason, as well as on account of his skill, a division of employments makes his labour more productive.

3. The invention of tools and machinery is the most effective auxiliary of labour, and it is necessarily promoted by a division of employments. Those who are constantly attending to one business or description of labour must become best acquainted with its requirements—their observation and experience are concentrated upon it—their interest urges them to facilitate their own exertions. How many inventions are due to workmen employed in manual labour the history of the steam-engine and of the cotton manufacture will furnish examples; but it is not in the case of workmen alone that division of employments facilitates invention. Their employers also have their whole minds bent upon improving their business; and amidst the multiplication of trades arise engineers and machinists, whose sole business it is to construct, improve, and invent machinery, aided by all the lights of theoretical science. And this leads us to the fourth advantage of a division of employments.

4. If all men were doing the same thing, and working for themselves unaided by others, their condition would never be improved; but by following particular occupations, those who exert most skill and industry produce more than they require for their own subsistence, and reserve a fund for the employment of others. [CAPITAL.] And thus there grows up from the midst of the people a class of employers who direct the labour of others. Until labour is so directed and maintained by the previous accumulation of capital, it is comparatively ineffectual; and while a division of employments is a powerful agent in producing capital, the latter, in its turn, facilitates a further subdivision. Without it, indeed, a system of division can only be carried out imperfectly and to a very small extent. The growth of capital also gives to many men the glorious privilege of leisure, exempts them from the necessity of labour, and leaves them free to study, to reflect, to observe, to reason and investigate. From this class arise men of science and of letters—philosophers, statesmen, historians, poets. And even with these the apportionment of a peculiar province gives power to their minds, and expands their knowledge. Their natural talents are developed, and their aptitude for particular pursuits becomes as conspicuous in intellectual industry as that of other men in manual operations.

5. Adam Smith speaks of the importance of a division of employments as leading to the invention of machinery, but passes over its utility in using machinery effectually, when invented. Every part of a large machine requires workmen whose sole business it is to work in unison with its peculiar movement. So distinct are these various processes—so diverse their character—that in all large manufactures there is an extensive vocabulary of names by which operatives working in the very same factory are distinguished. Without such a subdivision of peculiar employments the most ingenious machinery would be useless: and thus while machinery multiplies distinct operations of labour, these are, in their turn, essential to its efficacy.

6. Adam Smith assigns the origin of a division of employments to the "trucking disposition" of mankind—to their "propensity to truck, barter, and exchange one thing for another" (b. i. c. ii.). This love of barter however is only a secondary cause: men have no natural taste for it; but use it as a means of obtaining the various objects which they desire. If they could obtain them without the trouble of barter, they would unquestionably not follow barter as an amusement, any more than they would work if they could get what they wanted without labour. So far, then, from the trucking disposition of men being the cause of a division of employments, it would appear that a division of employments is rather the proximate cause of commerce. For if all men worked in the same manner and produced the same things, there would be nothing to exchange: but as soon as men learn to devote themselves to the production of one commodity, the whole of which they cannot consume, they must exchange the produce of their labour with others, who have been producing objects which they desire to possess. This is an intelligible origin of barter and commerce—consistent with the natural propensities of mankind, and not requiring for its support the strained hypothesis that men have an innate disposition to truck. But a division of employments, like barter, is itself but a secondary cause; and both alike must ultimately be referred to the one original cause of all forms of industry—the desire of mankind to possess various enjoyments which are only to be gained by labour.

This would appear to be the natural course of social progress. First, a man applies himself to a particular business because he has facilities for following it. One man lives by the sea and is a fisherman; another lives near the forest and hunts game. Each could obtain more of this particular food than he requires for his own use, and may desire some little variety. Under these circumstances it is very natural that they should effect exchanges with each other—not for the mere love of barter—but for the love of food. But such an exchange could not be made between two men who both lived by fishing—nor between two others who both lived by hunting; for under such circumstances neither party would have anything to offer but that of which the other already had enough. It is perfectly true that without barter no extensive division of employments can exist; but it is clear that barter is the immediate effect rather than the cause of such division. Of the influence of commerce upon the division of employments we shall have to speak presently; but in this place it is sufficient to show that the production of different commodities beyond the immediate wants of those who produce them enables men to barter, by giving them something to offer in exchange; and that afterwards the advantages derived from barter are an encouragement to further production of the same kind.

When this state of things has been once established, men avail themselves of all the natural advantages of their several positions, and apply themselves to the production of those commodities for which they have peculiar facilities. In one country minerals can be drawn from the bowels of the earth in unlimited abundance; in another the fruits of the earth teem upon its surface—fostered by a genial climate and a fertile soil. The inhabitants of these countries naturally seek to develope the resources of the earth which are within their reach. They labour effectively and produce abundance of their particular commodities, which they give in exchange for other things which they cannot produce themselves, but which they desire to enjoy: and thus a division of employments, by the aid of an extended commerce, distributes over the whole world the advantages of soil, climate, situation, and mineral productions, obtained by the experience and skill of men who have adapted their talents to the circumstances of each country.

Having thus hastily enumerated the several ways in which a division of employments adds to the efficacy of human labour, and increases the enjoyments of men, let us inquire in what manner it is restrained and limited. It may be collected from several of the preceding remarks, that the power of distributing men into particular employments must be limited by the extent of the market in which the produce of their labour may be exchanged. When there are no means of exchanging, men must provide everything for themselves that they require; and there is no further division of employments than that which necessarily takes place in families, and in the most simple forms of industry. So in every degree in which the situation and circumstances of men give facilities of exchange, do particular employments become assigned to individuals. A village draper sells all kinds of drapery, together with hats, shoes, coats, smock-frocks; nay, in some villages there is but one shop, in which nearly every kind of trade is carried on. In a populous city, on the other hand, trades are almost indefinitely subdivided. And why is this? Solely because of the extent of the market. In the one case, if a man sold nothing but hats, he could not gain a livelihood, and therefore he sells coats, smock-frocks, shoes, and all kinds of drapery—everything, in fact, which the people round about him are likely to buy. In the other case, there is so large a demand for hats, that a man can gain a better livelihood by the exclusive sale of them, than by a heterogeneous trade like that of the village shopkeeper.

But while, by means of exchange, employments are thus subdivided, the labour of many men is most efficiently combined in producing particular results. The combinations of industry for one object are often truly wonderful, while the employments of those who are really co-operating with one another are so distinct that they are wholly unconscious of any combination at all; nor is their combination at once perceptible to others. If you ask a man "who made his coat?"—he will naturally answer "his tailor." But ask him to enumerate the persons who had contributed to its production, and he will pause long before he attempts any answer, however incomplete. He will be reminded of the grazier, the shepherd, the wool-salesman, the various workmen in the cloth factory—the button-makers, the manufacturers of silk, and thread, and needles: but still the catalogue will be imperfect. In producing the raw materials, and in conveying, selling, and manufacturing them, the diversity of occupations is extraordinarily great. Each man attends to his own business, and scarcely thinks of its relations to the business of other people; and yet all are co-operating in the most effectual manner, for the most perfect and economical manufacture of this finished work of varied art.

The general operation of the principles of a combination of labour and division of employments has now been sufficiently explained so far as it relates to the efficiency of human industry. Of its effects upon the distribution of wealth (another important branch of political economy) no more need be said, than that by multiplying the modes in which industry is made productive, it is the main cause of the various grades of society which exist in all civilised countries. The different employments of men determine their social position as labourers or employers of labour; and the wealth arising from the effective employment of labour is distributed, through the several classes, as rent, profits, and wages.

It has been urged as an objection to an extended division of employments, that it unfits men for any change of business which altered circumstances may require; and that, on that account, great misery is caused when the demand for any particular kind of labour is reduced. Of this position the hand-loom weavers of England and Scotland are a familiar example, who are said to have been thrown out of employment by the extension of machinery. That they have been reduced to great distress is certain; but in their employment there was nothing to unfit them from engaging in power-loom weaving. On the contrary, the transition from one employment to the other would have been perfectly natural; but they preferred their independent life to the discipline of a factory, and for that and other reasons persisted in continuing in their old trade. In the mean time thousands of agricultural labourers and their families, whose occupations had been totally dissimilar, flocked into the manufacturing districts, and readily learned their new business. This example, therefore, instead of sustaining the objection, proves that a division of employments does not disable men, so much as might be expected, from transferring their labour to other departments of industry whenever a sufficient inducement attracts them. But any interruption or change in the ordinary course of industry is necessarily productive of temporary suffering to the working classes, from whatever cause it may arise; and an alteration in the forms of applying labour is but one out of many such causes. Yet much as this evil must be deplored, it is a satisfaction to know that it is only occasional, temporary, and partial in its operation, while the permanent welfare of mankind is promoted by all those means which render industry most productive and multiply the sources of human enjoyment.

Another objection to a minute subdivision of employments is, that it reduces vast masses of men to the condition of organised machines, uses them like tools, and uses them as such merely because machines have not yet been invented to do their work. From these facts, which are, to a certain extent, undeniable, it is inferred that the moral and intellectual character of men is degraded. This inference, however, is not supported by experience. Agricultural employments are less subdivided than trades and manufactures; but no one will contend that the farm labourer is ordinarily more intelligent than the operative, or that his morals are decidedly superior. In comparing their relative condition, we shall be led into error if we confine our attention to the influence of a division of employments. In the lower departments of labour the work is rarely of a kind to enlarge the understanding, whether it consist of a combination of several occupations or of one only; and in either case the greater part of a man's time is engaged in his daily work. It is therefore to the circumstances by which he is surrounded, rather than to the nature of his work itself, that we must generally refer his condition. In thinly peopled countries there can be comparatively little division of employments, and in populous cities the principle of division, for reasons already explained, is carried very far. In the one case the intercourse of persons with each other is very confined, and is enlivened with scarcely any variety; in the other case persons are crowded together, and brought into continual intercourse. These opposite circumstances produce different results for good and for evil. The intelligence of mankind is unquestionably increased by extended intercourse with one another: their morals, at the same time, are more liable to corruption. In large cities they are exposed to more temptations—they are under less restraint; and above all, they have, almost universally, higher wages, which enable them to indulge their propensities more freely. Much of the intellectual disparity of rural and town populations might be removed by an efficient system of education, by which men would be better qualified to observe and reflect upon the objects by which they may be surrounded; and great would be the moral influence of education in rendering high wages innocuous, by offering liberal sources of recreation to the operative, more attractive than the temptations of vice.

But to all objections it may be answered, that a division of employments is an imperative law of civilisation. Where land is abundant, families naturally scatter themselves over it, and provide for themselves nearly all that they want. More than they want they do not produce, as there is no market; and the growth of capital, under such circumstances, is impossible. But where land becomes scarce and dear, men are forced into other employments distinct from agriculture; capital grows, wages are offered as an inducement to work, and the more wealthy and populous a country becomes, the more extensive must be the distribution of separate employments. To object to a division of employments, therefore, is no less than to object to civilisation altogether; for the two conditions are inseparable. It is deeply to be lamented that many evils have hitherto clung to the progress of civilisation, which are not its necessary accompaniments. Many of them may be referred to the slow growth of political science, and might be corrected by the application of sound principles of government; many may be attributed to the neglect of the religious and moral culture of an *increasing* population: but short indeed must be the sight of any man who would seek to correct them by applying to a civilised state the rude expedients of barbarism.

DIVORCE (*divórtium, a divertendo*, from diverting or separating) the legal separation of husband and wife. The question of the legal dissolution of marriage has, after several commissions and much discussion, been settled by the British legislature by the 20 & 21 Vict. c. 85. It was enacted, that a court should be constituted in the name of the sovereign, to be called "The Court for Divorce and Matrimonial

Causes," such court to possess all the jurisdiction which the ecclesiastical courts have exercised in respect of divorces *à mensâ et thoro*, suits of nullity of marriage, restitution of conjugal rights, or jactitation of marriage. Thus the old form of proceeding for a separation from bed and board (*à mensâ et thoro*) is abolished, and for it is substituted the procedure for a "judicial separation," which is, in effect, a severance of the marriage tie, save that it does not enable either of the parties to marry again; but it places the woman in the same position as a *feme sole*, enabling her to hold and deal with property wholly free from the control of her husband; and in the case of the man, relieves him from all obligation to support his wife, and frees him from the possibility of having a spurious issue palmed upon him. But this court is armed with further power: it can absolutely separate man and wife so as to enable both of them to marry again. It can make provision for the injured wife according to the means of the guilty husband, by the name of "alimony." It can allow damages, if asked for, against the adulterer, and order him to pay the costs of the proceedings. It can, moreover, by the amending Act (22 & 23 Vict. c. 61), direct the custody of the children, and make such provision for the children of the marriage or their respective parents, out of any property which is the subject of ante- or post-nuptial settlement, as to the court shall seem fit. Thus the indissolubility of marriage is no longer maintained by the law of England. It is no longer necessary to resort to the legislature for a special Act of Parliament, preceded by a suit in the Ecclesiastical Court for a separation *à mensâ et thoro*, and an action against the adulterer for damages at common law, to obtain a divorce; but the wronged party may now at once, at no great cost, and with little delay, obtain relief from one of the most grievous evils of social life. It must, however, be said, that the wife cannot obtain a dissolution of her marriage (so as to enable her to marry again), unless the adultery of her husband is coupled with desertion of her for two years and upwards without reasonable cause, or with gross cruelty, or with bigamy, and some revolting offences; whereas the husband may obtain a divorce upon proof of his wife's adultery alone. In no case, however, will a divorce be granted if there has been collusion or connivance between the husband and wife with a view to obtaining a decree of the court. Nullity of marriage, although dealt with by the same tribunal as divorce, is distinct in its nature: it does not involve the dissolution of a marriage; but the object sought in such a proceeding is, an authoritative declaration that there never was any legal marriage between the parties, that it is null and void *ab initio*. The grounds of such a decree may be physical or mental incapacity to engage in such a contract, a previous marriage, consanguinity or affinity (in which is included marriage with a deceased wife's sister or husband's brother); also force, or fraud, or duresse to procure the marriage; also *error de personâ*, as where a person intending to marry one *individual* is actually married to another. Proceedings for restitution of conjugal rights may assume the shape of a suit for judicial separation, or even for a dissolution of marriage. The prayer for a direction to return to cohabitation may be met by the answer, that to do so would be dangerous to health or safety, or that adultery has been committed; either of which, if established, would justify the withdrawal from cohabitation: and in the one case, a decree of judicial separation would follow; and in the other, that of a dissolution of marriage.

Such is a brief summary of the change made in the matrimonial law of England. Scotland still retains its own peculiar laws on this subject; and Ireland is not as yet affected by the alteration of the law of England. And since so great an innovation has been introduced, it may not be out of place to notice the light in which the contract of marriage has been viewed by ourselves and some other nations.

From the curious document preserved by Selden ('Uxor Ebraica,' c. xxx., vol. iii., 845, folio ed. of his works), whereby John de Cameys, in the reign of Edward I., transferred his wife and her property to William Paynel; and also, from the reference to the laws of Howel the Good, at the end of this article, it would seem that, in the early periods of English law, a divorce might be had by mutual consent; but all trace of such a custom is lost.

By the common law of England marriage was a civil contract, and the ordinary courts of justice asserted their jurisdiction over this as well as every other description of contract. At length, the rite of marriage having been elevated to the dignity of a sacrament by Pope Innocent III., 1215, the ecclesiastical courts asserted the sole jurisdiction over it. And notwithstanding it was divested of that high character at the Reformation, it still remained in the eye of the law a religious contract, necessary to be celebrated by some formal rites wherein the priest was to officiate; and generally, except under special exemption, necessarily within the walls of a sacred edifice; wherefore it was that the ecclesiastical courts treated the matrimonial tie with such reverence, and the law of the land deemed the contract indissoluble, thus rendering it necessary to resort to the legislature for a special act of parliament to set aside a marriage. It was not, however, without doubt and much discussion that the opinion that marriage was indissoluble was arrived at by the early reformers. In the reign of Edward VI., Parr, the Marquis of Northampton, obtained a divorce in the Ecclesiastical Court by reason of the adultery of his wife, a commission (over which Cranmer presided) was appointed to inquire whether he could marry again; but before a decision was given he did marry again. The commissioners afterwards answered, "That the bond of wedlock being broken by the mere act of infidelity, the second marriage was lawful." The Marquis, however, applied for and obtained an act of parliament confirming the marriage. But the act was repealed in the following reign (that of Mary). In the following reign of Elizabeth was renewed the endeavour (which had failed in the reign of Edward VI.) to frame such laws ecclesiastical as should be thought convenient, under the name of "Reformatio legum;" one of those laws, "de adulteriis et divortiis," allowed a marriage to be dissolved by the ecclesiastical judge for adultery, desertion, long absence, mortal enmities (shown in overt acts, such as threatening life), lasting cruelty of a husband towards his wife. In all these cases the innocent party, whether wife or husband, might marry again. Severe penalties were denounced against adulterers, and the *divorce à mensâ et thoro* was abolished, but this code of laws never received royal confirmation, and therefore did not become law, and the question whether a complete divorce could be decreed by any strictly legal tribunal remained undetermined until the year 1571, when it was decided in the "Star Chamber" (a tribunal, although most arbitrary and despotic, still of binding authority), in a case known as "Foljambe's case," that the second marriage of a husband divorced from his first wife by reason of her incontinency, was still a void marriage, because the first divorce was only *à mensâ et thoro*, and not *à vinculo matrimonii*, (that is, the bond of marriage), reverting to the old ecclesiastical theory—that a marriage could not be dissolved by the spiritual court, which alone had cognisance of the matter. In 1603, under the auspices of James I., the canons which still regulate and bind the clergy were enunciated. In one of them (the 107th) it is declared that parties separated *à mensâ et thoro* shall not during each other's life contract matrimony with another person, consequently any clergyman of the established church would, apart from any other legal consequences, have been amenable to ecclesiastical censure and punishment had he knowingly performed the ceremony of marriage where either of the parties to such marriage had been separated by a mere divorce *à mensâ et thoro*.

To satisfy the scruples of the clergy, a proviso has been inserted in the act (20 & 21 Vict., c. 85, s. 57) that "no clergyman in holy orders of the United Church of England and Ireland shall be compelled to solemnise the marriage of any person whose former marriage may have been dissolved on the ground of his or her adultery, or shall be liable to any suit, &c., for refusing to solemnise the marriage of any such person." The next section provides that in the case of any minister's refusal any other minister may perform the service.

In the reign of Charles II., a loose and profligate period of our history, the aid of the legislature was sought to enable Lord Roos, who had obtained a divorce *à mensâ et thoro*, to marry again. Although the bill was strongly opposed, it passed, but it is said by the historians (Burnett among others), that there was a strong political bias in its favour with reference to the king's being divorced and re-married, with a view to bar the Duke of York's succession to the crown. Here, however, the legislature did not dissolve the marriage, but about thirty years afterwards an actual dissolution of the nuptial tie was enacted in the case of the Countess of Macclesfield, the reputed, if not the actual, mother of Savage the poet. Three years after this followed the Duke of Norfolk's case; and immediately afterwards that of a Mr. Rox. Thus the privilege was no longer confined to those in high places; the right to obtain an act "to dissolve a marriage and to enable the petitioner to marry again" (that is if the husband), became established, provided a person were rich enough to bear the costs of the application.

The causes admitted by various codes of laws as grounds for the suspension or dissolution of the contract of marriage, as well as the description of the tribunal which had, or in some degree has, jurisdiction over the proceedings, are various, and indicative of the degree of civilisation of the nations among whom they prevailed.

According to the law of Moses (Deut. xxiv. 1), "When a man hath taken a wife, and married her, and it come to pass that she find no favour in his eyes, because he hath found some uncleanness in her: then let him write her a bill of divorcement, and give it in her hand, and send her out of his house." After ninety days, the wife might marry again; but after she had contracted a second marriage, though she should be again divorced, her former husband might not take her to be his wife. The form of a Jewish bill of divorcement is given by Selden, 'Uxor Ebraica,' lib. iii., ch. 24; and see Levi's 'Ceremonies of the Jews,' p. 146.

As the customs of Oriental nations do not change, we may conclude that the usages in the matter of divorce now existing in Arabia are the same, or nearly so, as when Mohammed endeavoured to reform them among the tribes for which he legislated. An Arab may divorce his wife on the slightest occasion: he has only to say to her, "Thou art divorced," and she becomes so. So easy and so common is this practice, that Burckhardt assures us that he has seen Arabs not more than 45 years of age who were known to have had 50 wives; yet the Arabs have rarely more than one wife at a time.

By the Mohammedan law, a man may divorce his wife orally and without any ceremony; when this is done, he pays her a portion, generally one-third of her dowry. He may divorce her twice, and take her again without her consent; but if he divorce her a third time, or put her away by a triple divorce conveyed in the same sentence, he cannot receive her again until she has been married and divorced by another husband, who must have consummated his marriage with her.

For fuller information as to the Jewish and Mohammedan law of divorce, see Sale's 'Koran;' Lane's 'Modern Egyptians;' Hamilton's 'Hedaya,' and the 'Mishcat ul Masabih;' Selden's 'Uxor Ebraica;' and see the case of Lindo *v.* Belimario, 1 Hagg. 'Consy. Rep.' 216, before Lord Stowell.

Among the Hindoos, and also among the Chinese, a husband may divorce his wife upon the slightest grounds, or even without assigning any reason. Some of the rules mentioned by the Abbé Dubois, as laid down in the 'Padma Purana,' one of the books of highest authority among the Hindoos, show their manner of thinking concerning the conduct of their wives. The reasons for which, according to the Brahmanic law, a man may divorce his wife, may be seen in Colebrooke's 'Digest of Hindoo Law,' vol. ii., p. 414, &c., 8vo. edit.; and Kalthoff, 'Jus Matrimonii veterum Indorum' (Bonn, 1829, 8) p. 76, &c.

The laws in the several Grecian states regarding divorce were different, and in some of them men were allowed to put away their wives on slight occasions. The Cretans permitted it to any man who was afraid of having too great a number of children. The Athenians allowed it upon small grounds, but not without giving a bill containing the reasons for the divorce, to be approved (if the party divorced made an appeal) by the chief archon. The Spartans seldom divorced their wives; indeed the ephori fined Lysander for repudiating his wife. Ariston (Herod. vi. 63) put away his second wife, but it seems to have been done rather to have a son, for his wife was barren, than according to the custom of the country. Anaxandrides (Herod. v. 39) was strongly urged by the ephori to divorce his barren wife, and on his not consenting, the matter was compounded by his taking another wife: thus he had two at once, which Herodotus observes was contrary to Spartan usage.

By the laws of the early Romans, the husband alone was permitted to dissolve the marriage, but not without just cause, and a groundless divorce was punished by the forfeiture of the husband's effects, one-half of which went to the wife. Adultery, drunkenness, or counterfeiting the husband's keys, were considered good causes of divorce. (Dion. 'Hal.' ii. 25; 'Gellius,' iv. 3; Plutarch, 'Vit. Rom. et Num.') For about 500 years after the foundation of the city there was no instance of this right being exercised by the husband; but afterwards divorces became very frequent, not only for sufficient reasons, but on frivolous pretexts, and the same liberty was enjoyed by the women as by the men.

The maxim of the civil law was, that matrimony ought to be free, and either party might renounce the marriage union at pleasure. It was termed *divortium sine causâ*, or *sine ullâ querelâ*, that is, divorce without cause, or without question; and the principle, *bonâ gratiâ matrimonium dissolvitur*, matrimony is dissolved at pleasure, is solemnly laid down in the pandects. The abuse of divorce prevailed in the most polished ages of the Roman republic, though as has been said, it was unknown in its early history. Voluntary divorces were abolished by one of the *novels* of Justinian, but they were afterwards revived by another *novel* of the Emperor Justin. In the *novel* restoring the unlimited freedom of divorce the reasons for it are assigned; and while it was admitted that nothing ought to be held so sacred in civil society as marriage, it was declared that the hatred, misery, and crimes, which often flowed from indissoluble connections, required as a necessary remedy the restoration of the old law by which marriage was dissolved by mutual will and consent. This practice of divorce is understood to have continued in the Byzantine or eastern empire till the 9th or 10th century, and until it was finally subdued by the influence of Christianity.

On a divorce for infidelity, the wife forfeited her dowry; but if the divorce was not made for any fault of hers, her whole dowry was restored, sometimes all at once, but usually by three different payments. In some instances, however, where there was no infidelity on the part of the wife, only part was restored. On the Roman divorce and dowry, see 'Dig.,' xxiv., tit. 2, 3.

Among the ancient Britons, it may be collected from the laws of Howel the Good, that the husband and wife might agree to dissolve the marriage at any time, in which case, if the separation took place during the first seven years of the marriage, a certain specified distribution of the property was made, but after that period the division was equal. No limit was set to the husband's discretion in divorcing his wife, but the wife could only divorce her husband in case he should be leprous, have bad breath, or be impotent, in which cases she might leave him and obtain all her property. The parties were at liberty to contract a fresh marriage; but if a man repented of having divorced his wife, although she had married another man, yet if he could overtake her before the consummation of the marriage, or, as the law expresses it, "with one foot in the bed of her second husband, and the other outside," he might have his wife again.

Adultery was punishable by fine.

The laws of Scotland relating to divorce differ widely from those existing in England: there, a divorce *à vinculo matrimonii* is a civil remedy, and may be obtained for adultery (but the guilty parties cannot intermarry), or for wilful desertion by either party, persisted in for four years, though to this a good ground of separation is a defence. But recrimination is no bar to a divorce as it is in England.

In the Dutch law there are but two causes of divorce *à vinculo matrimonii*,—namely, adultery and desertion.

In Spain the same causes affect the validity of a marriage as in England, and the contract is indissoluble by the civil courts, matrimonial causes being exclusively of ecclesiastical cognisance. ('Instit. Laws of Spain.')

The law of France, before the Revolution of 1792, following the judgment of the Roman Catholic Church, held marriage to be indissoluble; but the legislators of the early revolutionary period permitted divorce at the pleasure of the parties, even where incompatibility of temper alone was alleged. This, however, led to a great abuse of the privilege. The Code Napoleon accordingly restricted the liberty, but still allowed either party to demand a divorce on the ground of adultery committed by the other; for outrageous conduct, or ill usage; on account of condemnation to an infamous punishment; or by mutual consent, provided it was formally declared by both that their life was insupportable. By the same code, a woman could not contract a new marriage until the expiration of ten months from the dissolution of the preceding. Adultery is now treated in France as a criminal offence.

It must be borne in mind, however, that the Roman Church, for the purpose of increasing its revenue, has at all times claimed the right to dissolve marriage by dispensation; and therefore this power of divorce still exists in France, and all Roman Catholic countries, independent of the law of the land.

In the United States, marriage, though it may be celebrated before clergymen as well as civil magistrates, is considered as a civil contract. The causes of divorce, and the power of obtaining it, are by no means the same in the several states. Nullity of marriage is decreed on the ground of a former marriage, physical incapacity, consanguinity, or fraudulent contract, by the Connecticut law; and by the New York code, idiotcy and insanity, and either party being under the age of consent. Adultery is a cause of divorce *à vinculo matrimonii*; and the laws of some of the states prohibit the guilty party from marrying again. If the husband or wife is absent seven years, or, by the laws of some states, three years, and not heard from, the other is at liberty to marry again; and in some states, if the husband desert the wife, and make no provision for her support during three years, being able to make such provision, the wife can obtain a divorce. Extreme cruelty in either party is also generally a cause of divorce *à vinculo matrimonii*. In many of the states, applications to the legislature for divorce, in cases not provided for by the statutes, are very frequent. In New York and New Jersey, divorce is a subject of Chancery jurisdiction, from which, as in other cases, questions of law may be referred to a jury for trial. In New Hampshire, joining the religious society of Shakers, who hold cohabitation unlawful, and continuing in that society for three years, is sufficient cause for a divorce. But in most of the states, the courts of law have cognisance of divorce. The laws prescribe the provision to be made for the wife in case of divorce, confiding to the courts, however, some degree of discretion in fixing the amount of alimony.

It will thus be seen that the law regulating divorce is by no means uniform throughout the United States, and ofttimes embarrassing questions arise when a marriage is had in one State, and a divorce in another. See Bishop on *Marriage and Divorce*; and Story's *Conflict of Laws*; and Kent's *Comm.*; *Ency. Americ.* Upon the general advantages of indissolubility, as opposed to an unlimited right of divorce, see Hume's *Essay on Polygamy and Divorce*; Paley's *Moral Philosophy*; and the judgment of Lord Stowell in Evans *v.* Evans, 1 Hagg. *Consy. Repts.*, 48; Milton's treatise on divorce; and Gibbon, *Decl. and Fall*, c. 44.

DIWÂN. [DIVAN.]

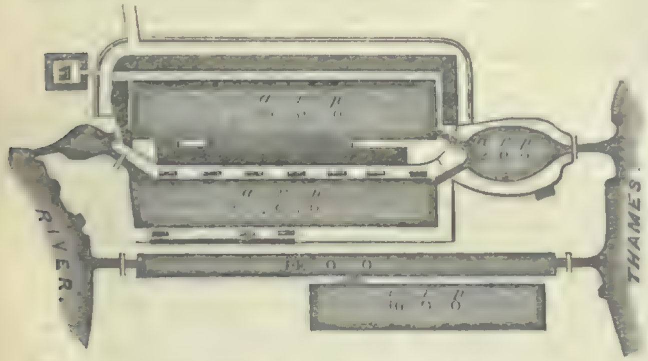
DO, in music, the name given by the Italians and the English to the first of the syllables used in solmization, or solfaing, and answering to the *ut* of the French.

DOCK. An enclosure from a water surface resorted to by shipping, in which the latter can lie in safety from the various accidents attached to rivers or arms of the sea in their natural state, or in which the operations of loading and unloading can be performed without being interfered with by the variations of the water level. Of late years, however, the generic term "dock" seems to have been more particularly applied to the enclosures which are surrounded by bonding warehouses, whilst the simpler enclosures of this description which are not so surrounded are distinguished as "basins." The enclosures specially appropriated to the repairs of ships, "in the dry," are known by the name of "dry docks," or "graving docks."

The construction of docks, with the express intention of maintaining the water in them at such a level as to keep the ships constantly afloat, is of comparatively very recent date: for the Mediterranean, upon which nearly all the commerce of the ancient world was carried on, presents very little difference of level at the various times of the tides; and indeed the class of vessels employed in trade by the ancients was not of such a size or so constructed as to render it indispensable that they should always be kept afloat. About the beginning of the last century the size of merchant vessels began to increase; and it was then found that, especially in such ports as Liverpool, they were exposed to receive serious injury from the periodical "beaching" they were compelled to undergo, in consequence of the fall of the tides and the shallowness of the water near the shore.

Under such circumstances, therefore, the port authorities of the districts alluded to directed their attention to the creation of closed basins wherein the vessels might ride in safety; and it was at Liverpool that the first recorded great works of this description were executed, by the formation in the year 1710 of the dock at present known by the name of the Old Dock, and of the St. George's Dock, in 1762. The system thus inaugurated was found to be so advantageous that it was followed rapidly by other commercial towns, but it was not until the commencement of the present century that the metropolis of England followed the example; when, however, it did so, the great improvement of surrounding the basins with bonded warehouses was likewise introduced, and the complete modern system of docks was, for perhaps the first time, applied in the West India and the London Docks, respectively opened in 1802 and 1805. Nearly all the best modern docks have been constructed upon this system, and it has even been copied in foreign countries; for the Entrepôt Dock of the port of Hâvre, and the new docks of Marseille, are built with all the accessories to be found in the London establishments of this nature.

Leaving out of account for the present the docks exclusively devoted to one particular class of traffic, such as the coal docks of the North of England and of Wales, it may suffice to say that in tidal rivers, where the variations in the height of the water are great, it is desirable to form, immediately behind the exit or the entrance lock gates, a half-tide basin wherein vessels of small draught may lie until the level of the water on the outside shall rise to such a height as to allow of their movements being carried on. The entrance to the dock basin itself should be placed at the upper end of the half-tide basin; and it is desirable that all the locks should have double gates, pointing respectively up and down stream. If, in consequence of the Customs regulations of the country, it should be necessary to form import and export docks, it would also be desirable to place the gates leading to and from them at the upper end of the half-tide basin, which in such cases must be made wide enough to allow the various movements of the vessels to take place without their being crowded; and, as a general rule, it may be said that the import dock should be situated on the left and the export dock on the right-hand side. The basins, in such cases as supposed, should communicate at their upper ends only; and the vessels should, after being unloaded, be warped through the lock or communication channel to the berth where it is to take in its cargo. Notwithstanding some practical defects in its details, the plan of the West India Docks, as originally designed by the late Mr. J. Rennie, was one of the most logical of any which has been hitherto suggested—that is to say, for ports where the Customs regulations are rather vexatious—and as such it is here introduced.



WEST INDIA DOCKS.

If these leading principles are carefully borne in mind, the details of execution of a dock may be modified to suit local circumstances, and in such cases as Bristol, Ipswich, &c., the formation of these marvellous facilities to commerce may be made conducive to the improvement of the navigation itself. In both the cases mentioned, old branches of the rivers were operated upon, in which the stream naturally followed very tortuous courses, and thus lost a portion of its power of transmitting the tidal wave to the interior; by cutting new and straight courses for the streams, and by converting the old channels into closed basins, not only was a considerable area of water surface made available for the purposes of trade, but the "regimes" of the rivers were rendered more stable and better fitted for traffic purposes. There is a further advantage attending such a conversion of the bends of rivers, namely, that generally speaking in such cases it is possible to make locks at both ends of the chord of the arc formed respectively by the new cut and by the enclosed water surface; but it is impossible to lay down any invariable rule in a matter which must admit of so many modifications in consequence of the physical and commercial conditions of the places under consideration.

The only invariable laws with respect to the formation of docks appear to be that, 1st, the area of water surface should be as small as possible in proportion to the development of the quay walls. 2nd, If a simple parallelogram be the form adopted the width may be calculated upon the principle that, *at the maximum*, three tiers of ships might lie alongside the quays on either side, and that there should be a sufficient space between the outer tiers to allow a vessel to swing round: the widths and lengths which form the basis of this calculation would of course depend on the class of vessels frequenting the harbour or river. 3rd, The whole of the basins and of the warehouses, courts, yards, quays, &c., should be securely enclosed, both for the purposes of the fiscal relations of the port and for the protection of the merchandise there unloaded: it was, indeed, principally on account of the robberies committed on the Thames and in the warehouses alongside the river that the docks of London were originally proposed. 4th, The depth of water in the floating basin must be such as to allow the vessels to float at all times of the tides; in many cases, as at Hâvre, for instance, the necessity for observing this precaution has rendered it indispensable to sink the bottom of the basins considerably below the level of the bed of the sea in the outer harbour. It is desirable also, in order to avoid inconvenience from rapid silting up of the basins, to allow originally a depth rather in excess of that which is theoretically required. 5th, If the docks should be constructed in such positions as to allow vessels to sail directly into them, they must have an outer harbour sufficiently long and secure in which the vessels may loose their "way," or the impetus of advance, before they approach the half-tide basin or the inner lock.

The details of the quays, and of the sheds and warehouses, must depend upon the character of the trade at the particular place under consideration, and upon the customs regulations of the country. As a general rule it would, however, appear to be preferable to make, on the immediate edge of the quay, a paved road or gangway, of about 20 feet in width, without any roofing, and to place on this gangway the cranes for unloading or loading. It is found, indeed, that goods arriving from great distances, whether by land or by sea, require that their cases or envelopes should be examined and repaired before the goods are transmitted or shipped. This operation is sometimes known by the phrase *coopering*, and the open space above recommended, affords facilities for its execution, as well as for the operation known under the name of *sampling*, and for the examination by the custom house officers. Immediately beyond this open space it is customary to erect a shed of at least 30 or 40 feet clear width, in which goods for immediate delivery may lie for a few days, and in which the export goods may be received, if the regulations of the port should be such as to allow the ship to discharge, and receive, cargo on the same berth. The shed is usually succeeded by a wide road, of from 40 to 60 feet, along which the waggons engaged in the service of the dock can circulate; and beyond this road are the warehouses wherein goods are bonded or stored. These warehouses are usually made from 100 to 120 feet wide, and of from one to six stories in height, each of about 11 feet from floor to underside of beams, according to the description of goods they are intended to receive; for it may be as well here to state that tobacco is usually stored in sheds of only one story; sugar (especially the West Indian sugar) is stored in warehouses of three stories; wool is stored in those which have four stories; teas, silks, drugs, spices, &c., in warehouses of about five or six stories. Naturally, however, the number of stories will depend also to some extent upon the value of the ground, and the price of labour in the particular position; for as a general rule it is not desirable to concentrate too much merchandise of value under one roof. The settlement of these details of construction requires great skill, and an intimate knowledge of commercial affairs, in order to secure both economy of construction and of subsequent working.

It may be added that the area of warehouse floor occupied by the various classes of goods varies from 12 feet superficial per ton, of heavy goods, such as sugar in casks piled in two tiers, and including the necessary passages; to about 50 feet superficial per ton of wool, cotton, &c., also packed in two tiers. Wines and spirits are better kept in cellars than above ground; but wherever they are kept, precautions must be observed to maintain a constant temperature around them, and to prevent accidents by fire. In the London Docks, no artificial lights are allowed to be introduced into the spirit cellars or stores.

Beyond the warehouses thus described, it is desirable to form a roadway, at least 60 feet wide, for the waggons which are to receive the goods cleared for consumption, and for any connection with the general railway system of the country which may be desired. The whole of these roads, warehouses, basins, &c., should be surrounded by a wall of at least 20 feet in height.

The St. Katherine's Dock, and the Albert Dock of Liverpool, have been constructed upon principles rather different from those described above, for the warehouses are carried up perpendicularly from the edges of the quays, without any intermediate sheds and roads. This modification was rendered necessary, in the case of St. Katherine's Dock especially, by the extraordinary value of the land on which it was built; but unquestionably the manipulation of the merchandise, under these circumstances, is carried on at a greatly enhanced cost, and with great confusion. In the St. Katherine's Dock there are in some of the warehouses also seven stories (counting the entresol as one); but it is worthy of remark, that merchants have so great an objection to the use of the upper story that practically it is of no value. A very important condition to be observed in the construction of dock ware houses is, that the ventilation should be entirely under control; for if the circulation of air be too rapid, a dessication, and a consequent loss of weight, in the merchandise would take place; whilst, on the other hand, if the air were kept stagnant, some classes of goods would deteriorate.

St. Katherine's Docks.

In docks more especially devoted to the purposes of the timber trade very different arrangements are required from those above described. As the ordinary baulk, fir timber, is supposed to improve by being kept for a certain time afloat, the water surface of timber docks must be made greater than usual, in order to allow the timber to be rafted. The deals and planks require a considerable area for piling, but they do not require any sheds; and the ordinary manner of unloading them, namely, through ports in the bows of the ship, renders necessary a trifling modification in the form of the quay walls. Mahogany and fine furniture woods, however, require to be stacked under sheds, and those of the West India Docks may be cited as models for this class of structure: they contain a series of moveable cranes, erected by the late Mr. J. Rennie, which might even now serve as valuable lessons to engineers and machinists.

It must be distinctly understood that the remarks above made upon the practical details of dock construction, are made with reference only to the circumstances of the day (1859); and it may be interesting to call attention to some of the circumstances which have already modified to a serious extent the technical laws affecting these matters. Thus, the West India and the London Docks were originally built at a time when the existence of a state of war rendered it necessary for merchant vessels to sail in convoys, and they frequently arrived in the Thames, under those circumstances, in great numbers. It was therefore necessary to make the water surface of the docks larger, in proportion to the development of quay front, than would have been necessary in time of peace, in order to be able to receive at once the whole fleets of a season. On the declaration of peace, it was found that the basins were too wide, and in some cases temporary jetties were run into them to increase the berth room; but upon the inauguration of Sir R. Peel's free-trade policy, the great water surface of these docks assumed a fresh value, from the fact that vessels laden with corn, rice, and other grains admitted free of duty, were obliged to unload into barges in dock, because the swell of the steamers in the open stream damaged the cargo. Under all these ever-varying circumstances, it would seem, nevertheless, that the most rational dimensions for parallel basins intended to receive ordinary sailing ships are, that the width should be made about from 500 to 600 feet, and the length about three or four or even six times the width.

The entrance locks of the docks at London vary in width, according to the traffic they are specially designed to accommodate, from 40 feet, to as much as 90 feet in the case of the new Victoria Docks. For ordinary shipping purposes a width of 48 feet, and a constant depth of water of 23 feet over the cills will suffice, and the enormous width of the Victoria Docks can only be required for the reception of sea-going paddle-wheel steamers. The clear length between the points of the gates likewise varies between 100 and 300 feet; but the length of the entrance to the East India Dock, 210 feet, seems to afford a very fair average. As to the quay walls, they may be built either with a curvilinear batter, in the style usually adopted by English engineers, or with a straight batter, as upon the continent; in both cases the versed sine is ascertained by making the average inclination equal to one in eight. The various communication bridges should be made to open in such a way as to interfere as little as possible with the rigging of the ships moving in the docks; and for this reason *turning* bridges are preferable to *lifting* bridges, or to those which are called *bascule* bridges. These remarks about the interference with the rigging will of course apply throughout the whole details of dock construction; and, indeed, the injury which is often done to the masts and yards of vessels lying in the St. Katherine's Dock, is one of the most serious objections to the system of erecting the warehouses on the edge of the quays.

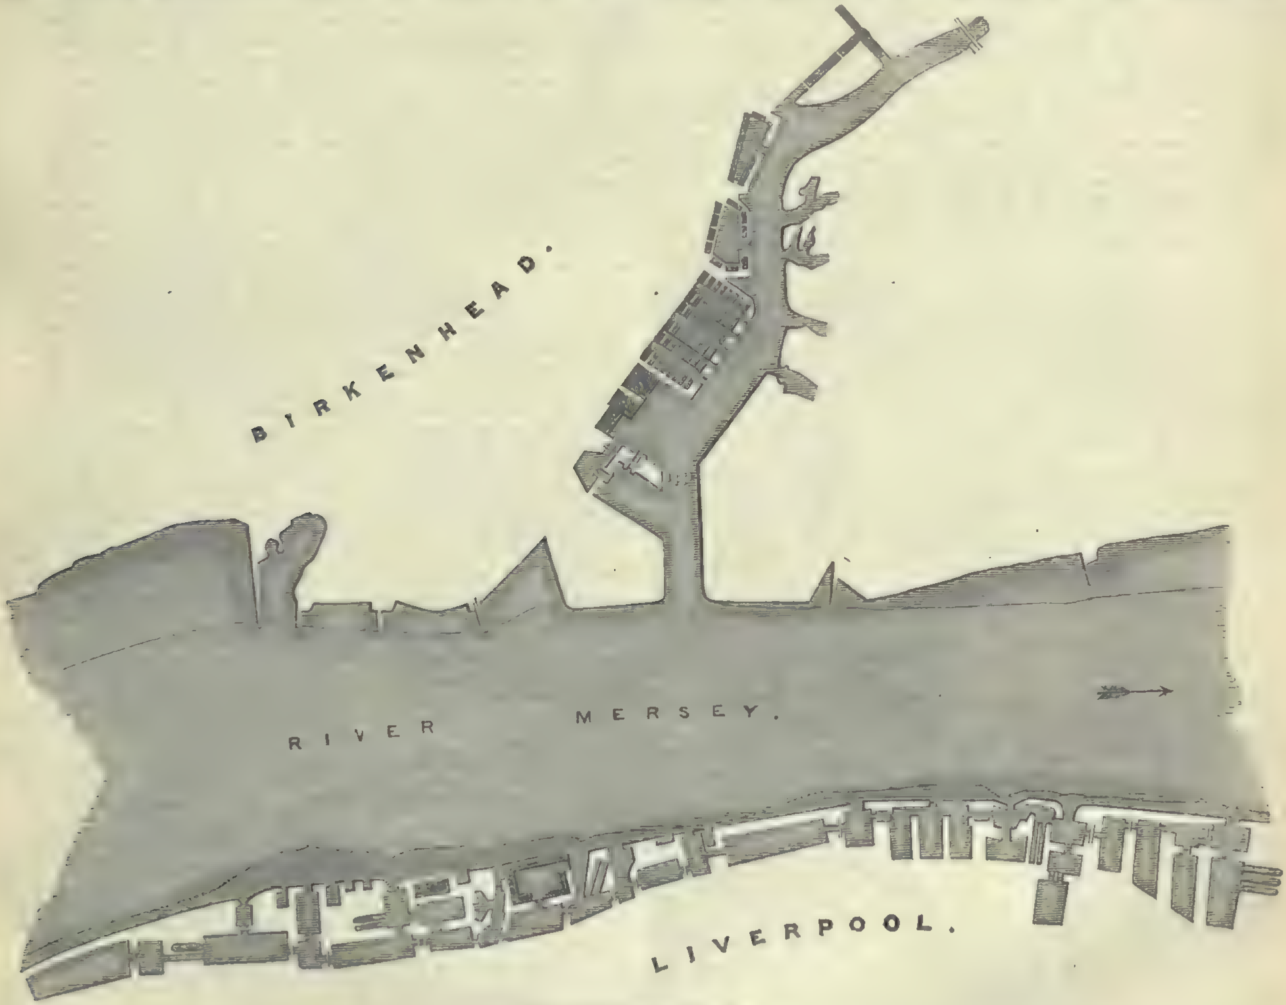
The quay walls must be protected by means of fender piles to prevent the ships from injuring the masonry as they rise and fall. A very solid heavy coping must be placed on the walls; bollards, or mooring posts, should be fixed at about every 50 feet apart; and a crane of about 5 tons power, and a water-cock or hydrant, placed at distances of 200 feet apart. It would be advisable, especially in a long dock, to make occasional provision for a ladder or staircase to the water's edge, in order to allow communication by boats between one side of the dock and another. In docks where repairs of ships are habitually executed, it may be necessary to devote a portion of the water and of the quay surface to this purpose, and to provide *shear-legs, masting-tackle, gridirons* or *caulking-lumps,* with the necessary furnaces for melting pitch and tar. Under all circumstances these latter furnaces must be kept at a considerable distance from the vessels in dock, and it is impossible to attach too much importance to the precautions to be observed for the prevention or for the extinction of fires. In the most recently-constructed docks for the reception of the coal traffic, the hydraulic lift has been largely employed; and, indeed, it has likewise been introduced in the working of the goods warehouses, both of the London and of the Liverpool docks.

Vessels entering docks, of course, do so under the direction of the dock-master. There is at the entrances of the London Docks a clear space left in the river (with a radius of 200 yards), where the companies place dolphins, or hauling buoys, to facilitate the manœuvres of the vessels about to enter. A red flag is hoisted at the pier head when it is time for the vessels to prepare to come in, and a blue flag is hoisted to show that the passage is free. Directly the ebb begins to make strongly, the blue flag is struck: when this is done, no vessel is allowed to enter until the next tide without a special order; vessels coming in have the precedence over those going out. All the manœuvres attending the entrances of the ships are performed by their own crews; and the captains are bound to see that the anchors are ataught, the boats on deck, the bowsprits run in, the yards set up and down, and generally that every precaution is taken to occupy as little space as possible. The regulations with respect to fires, and the working of the ships in dock, vary in every port; but, as a principle, it is admitted, that if goods are to be warehoused, none but the workmen employed by the dock authorities are allowed to touch them, under the inspection of the Custom-House officers and of the captains of the ships. In the case of goods discharged at once in lighters, *over side,* the dock authorities supply the necessary labour to the captains at a fixed tariff; but this operation is carried on entirely at the risk of the merchandise, and it must be performed with the rapidity required by the dock authorities.

The rates usually charged for the use of docks are: 1. The *landing rate,* which includes the quay rate, the unloading and entry into the stores, or the stowage on the quay, and the loading upon carts if the goods are removed immediately from the Customs scales. 2. The *consolidated rate,* which includes the quay rate, the entry into stores, the examination and repair of casks and packages, the sampling, the weighing on delivery, the certificates of damage, and rent for three weeks from the day of breaking bulk. 3. The *management rate,* which is supposed to cover the expenses of showing the goods to purchasers, and of preparing them for sale. 4. The *rent,* payable by weeks, or by fractions of weeks. From observations made upon the application of the rates of the various London companies, it would seem that they are not very logically arranged, and that the rent, especially, does not cover the expenses connected with it. Generally speaking, however, it may be said that the working expenses of the London docks are equal to about 60 per cent. of their gross receipts, and that they pay, one with another, about 4½ per cent. on the capital invested in them. It must, however, be here observed, that the trade connected with steam-boats does not pay the dock companies more than 2½ per cent. profit under the ordinary tariffs, and that graving-docks never yield much more than 2½ per cent. on their outlay. The price of the Liverpool Docks was said to have ranged between 24,000*l.* and 36,000*l.* per acre of land inclosed; and in that port it is by no means rare to work as many as from 25,000 to 28,000 tons per acre of water surface per annum, while the proportion in London is only from 5000 to 6000 tons per acre. As an approximate rule, the floor surface of the warehouses may be calculated at the rate of 10 feet superficial for every ton in store; but, as was said before, no invariable rule can be applied in this case. Goods generally remain in warehouse for about three months; but the lighter and more valuable goods remain there the longest.

On account of the great security of the warehouses of the larger and wealthy dock companies, it has been possible to introduce a very important facility for commercial operations by the creation of a class of securities known as *dock warrants.* These are, in fact, acknowledgments on the part of the company that they hold and are responsible for certain quantities of goods specified on the warrant, which is then transmissible by endorsement, and the goods are deliverable to the last holder, unless notice to the contrary should have been legally given. [DOCK WARRANT.]

The system of business adopted at Liverpool is rather different from that of London, even when, as in the Albert Docks, the basins are surrounded by bonding-warehouses; for, as a general rule, the commerce of the former town is carried on by means of basins, and of private warehouses in the upper part of the town. In the new Victoria Docks also, some modifications of a rather doubtful value have been introduced, which may be understood by reference to the accompanying cut. Almost every important port in England can now boast of its docks, and the details of them are so necessarily modified by local circumstances that it would be impossible to discuss them in a general article.



Plan of the Liverpool Docks.

DOCK-WARRANTS, are orders by the owner of goods which are lying at a wharf or in a warehouse, upon the wharfinger or warehouseman, to deliver up the goods, or a named portion of them, to the person or persons in whose favour the orders are made. Then if the owner wishes to sell the goods, or portion of them, he may, by handing the dock-warrant to the buyer, made out in his favour, transfer to him the right of obtaining the goods from the wharfinger or warehouseman; so the buyer, by endorsing to a sub-buyer, may transfer to him, and so on; but not so as to be enabled, without something more takes place, to bring an action against the wharfinger, &c., in case of refusal by him to deliver according to the warrant. These warrants, or delivery orders (as they are sometimes called), have the quality of securities, for they represent the goods themselves; and the warehouseman, accepting the order, and not refusing compliance on the ground that he holds the goods subject to an unsatisfied lien of his own against the original owner, or otherwise declining the order, becomes the agent of the buyer, and the buyer holding this order or warrant has the same right to go into the market and sell as if he had the goods in his pocket. Exceptions to, or modifications of, the rule may occur in cases of bankruptcy, insolvency, or when anything remains to be done with the goods before they are in such a state as to identity and quantity as the buyer bargained to have them delivered in; but the above is the general rule. In general, also, the right of lien which the seller has against the buyer is not made away with by giving a dock-warrant or delivery-order.

The wharfinger or warehouseman is liable to an action if he refuses to comply with the dock-warrant or delivery-order and hand over the goods, provided he has signified his acquiescence in the order when it was first presented to him, or have accepted rent, &c., or done any other act so as to have assumed the character of wharfinger to the person suing.

Various statutes have been passed for the better protection of persons making advances of money on goods, &c., on the security of documents of title of this kind, the last of which is the 5 & 6 Vict. c. 39; and see 12 & 13 Vict. c. 106, s. 179.

DOCTOR, one who has taken the highest degree in the faculties of Divinity, Law, Physic, or Music. In its original import it means a person so skilled in his particular art or science as to be qualified to teach it.

There is much difference of opinion as to the time when the title of Doctor was first created. It seems to have been established for the professors of the Roman law in the University of Bologna, about the middle of the 12th century. Antony à Wood says, that the title of Doctor in Divinity began at Paris, after Peter Lombard had compiled his Sentences, about the year 1151. ('Hist. and Antiq. Univ. of Oxford,' 4to. Oxf. 1792, vol. i. p. 62.) Previously, those who had proceeded in the faculties had been termed Masters only. The title of Doctor was not adopted in the English Universities earlier than the time of John or Henry III.

In Oxford the time requisite for the Doctor of Divinity's degree is eleven years from the time of matriculation, or four years from the time of proceeding B.A. Doctors of Civil Law, four years after proceeding through Arts, or if intending to practise in the Ecclesiastical Courts; if not, five years from the date of admission as B.C.L. For the degree of M.D., three years must intervene from the time of the candidate's having taken his Bachelor of Medicine's degree. For a Doctor's degree in Divinity or Law three distinct lectures are to be read in the schools, upon three different days: but by a dispensation, first obtained in convocation or congregation, all three are permitted to be read upon the same day; so that by dispensation a single day is sufficient in point of time for these exercises. For a Doctor's degree in Medicine, a dissertation upon some subject, to be approved by the Professor of Medicine, must be publicly recited in the schools, and a copy of it afterwards delivered to the Professor. The University fee on admission is 40*l.*

In Cambridge a Doctor of Divinity must be a Bachelor of Divinity of five, or a M.A. of twelve years' standing. The requisite exercises are one act, two opponencies, a Latin sermon, an English sermon, and a determination. A Doctor of Laws must be a Bachelor of Laws of five years' standing. His exercises are two acts and one opponency. Doctors of Medicine must be Bachelors of Medicine of five years' standing, or a M.A. of seven years' standing. The exercises are two acts and one opponency. For the degree of D.D., the total fees are 51*l.*; for LL.D., 25*l.* 10*s.*; for M.D., 15*l.* 10*s.* For a Doctor's degree in music, in both Universities, the exercise required is the composition and performance of a solemn piece of music, to be approved by the Professor of the Faculty. ('Oxf. and Camb. Calendars,' for 1859.)

Coloured engravings of the dresses worn by the doctors of the several faculties of Oxford and Cambridge will be found in Ackermann's 'History of the Univ. of Oxford,' 4to, 1814, vol. ii. p. 259, et seq.; and in his 'History of the Univ. of Cambridge,' 4to, 1815, vol. ii. p. 312, et seq.

DOCTORS' COMMONS, the College of Civilians in London, near St. Paul's Churchyard, founded by Dr. Harvey, Dean of the Arches, for the professors of the civil law. The official residences of the judge of the Arches' Court of Canterbury, of the judge of the Admiralty, and the judge of the Prerogative Court of Canterbury while it existed, were situated there; and it was the residence of the doctors of the civil law practising in London, who live there (for diet and lodging) in a collegiate manner, and common together. Doctors' Commons was burnt down in the fire of London, and rebuilt at the charge of the profession, whose modern representatives have been authorised to sell the property. [ARCHES, COURT OF.]

DODE'CAGON, a figure of twelve sides; a term generally applied to an equiangular and equilateral (or regular) dodecagon. [REGULAR POLYGON.]

DODECAHEDRON. [SOLIDS, REGULAR.]

DOEGLIC ACID ($C_{[illegible]}H_{[illegible]}O_{[illegible]}$). An oleaginous acid, extracted from the oil of a species of sperm whale, *Balæna rostrata* (Danish Dögling). It solidifies at 62° Fahr.

DOGE was the title of the first magistrate of the republic of Venice. The first settlers on the islands of the lagune were governed by magistrates sent from Padua. After Padua was devastated by the Huns and other barbarians, A.D. 452-60, the colonists of the lagune being left to themselves, each island elected a magistrate called tribune. An annual selection was made of seven from among these tribunes, who constituted the government of the whole community. A council of forty persons chosen by the general assembly of the people had the legislative and judicial powers. As population and wealth increased, and the community was threatened by hostile neighbours, it was found necessary to concentrate and strengthen the executive, and a chief magistrate for life was elected by the assembly of the people, and was called doge, a corruption of dux, as he was also general of the armed force. The first doge, Paolo Luca Anafesti, was elected in 697. The third doge in succession, Orso Ippato, elected in 724, made war against the Longobards, and took Ravenna, which he restored to the Byzantine emperor, who, as a reward for this service, granted to the republic a tract on the coast of the mainland as far south as the Adige. This first continental possession of Venice, being afterwards enlarged, was called Dogado. The successes of Orso inspired the people with jealousy, and he was assassinated in 737. The office of doge was at the same time abrogated, and an annual magistrate was substituted; but the fifth of these was imprisoned on some charge, and his eyes were put out, after which the people again elected a doge for life in 742. From that time till 1172 about forty doges ruled in succession, nearly one half of whom died a violent death, or were deposed, exiled, or had their eyes put out, sometimes by regular trial before the council of forty, and sometimes by popular insurrection. The Quarantia, or Council of Forty, which exercised the government during the interregna, assumed by degrees the power of electing a doge, in order to put a stop to the frequently recurring tumult and anarchy; the choice, however, was subject to confirmation by the assembly of the people. The first doge thus elected was Sebastiano Ziani, in 1173, and the Forty made him swear to a new constitution, or fundamental law, by which, instead of the general assembly of the people, the sovereign power was vested in a great council of 480 citizens, elected for one year, but capable of indefinite re-election. These were chosen by twelve tribunes, two for each sestiere, or district, of the city of Venice alone, who were themselves appointed by the inhabitants of their respective districts, the other islands and territories of the republic having no part in the elections; each tribune naming forty members. The Great Council was to appoint six individuals who were to be the doge's counsellors, without whose concurrence no act of the doge should be valid. This council was afterwards called "la Signoria." In important cases the doge was to consult with another council of sixty members, called Pregadi, or "requested," taken also from the Great Council. The citizens of Venice, weary of tumult, and being secured in the exclusive right of furnishing the members of the Great or Sovereign Council, seem to have willingly acquiesced in these constitutional changes, and a distribution of golden pieces made by the new doge served to gratify the populace. About a century after, another organic change took place. Pietro Gradenigo being elected doge in 1289, by the influence of the old or aristocratic families, proposed a law which passed the Great Council in 1298 after much opposition and delay, that no one should in future be eligible to sit in that assembly except those who then had a seat in it, or whose fathers, grandfathers, and great-grandfathers, had been members of it. The number of the members of the Great Council was no longer limited to 480. Lastly, in 1319, a new law passed the Great Council, by which that assembly declared itself permanent and hereditary, all the members who were then sitting in it (about 600 in number) remaining for life in possession of their seats, their sons who were above twenty-five years of age being likewise admitted, and their descendants after them, to the exclusion of all other families. This decree, known in history as "la serrata del maggior consiglio," established an hereditary and exclusive aristocracy at Venice, which lasted till the end of that republic. The celebrated Council of Ten was also then appointed, which, though at first only named for two months, gradually appropriated all the power of the state. The confirmation of the doge by the people was henceforth dispensed with. The doge himself became merely a state pageant, the servant of the councils, which had the power of trying and deposing him, and even sentencing him to death. They took away from him the command of the military and naval forces, his children were excluded from every office of state, and he had no patronage except the prebendal stalls of the cathedral of St. Mark. The doge was president by right of all the councils, with a double, or casting vote. He was simply addressed by the title of Messer Doge. ('Memori Venete' di Giovanni Gallicioli, Venice, 1826; Daru, 'Histoire de Venise,' books 6 and 39.)

The doges at Genoa were at first magistrates for life [BOCCANERA, in BIOG. DIV.], as at Venice, but the frequent contentions and civil factions among the aspirants to that dignity induced Andrea Doria, in his reform of 1528, to make the office of doge to last only two years. [DORIA, in BIOG. DIV.]

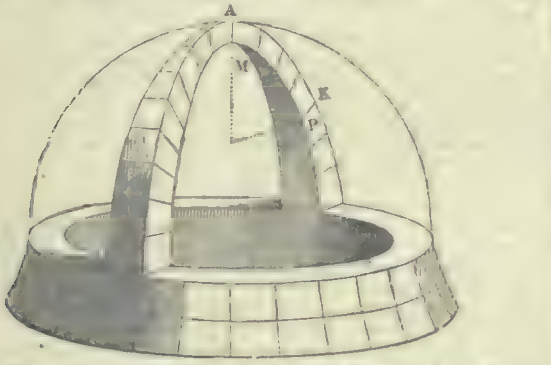
DOGMA (δόγμα), a word borrowed from the Greek, means an established principle, a fundamental article of belief derived from undisputed authority, and is generally applied to the essential doctrines of Christianity which are drawn from the Scriptures, or from the authority of the Fathers. Hence that branch of divinity called dogmatic theology is an exposition and assertion of the various articles of the Christian faith as founded upon authority acknowledged by Christians in general, and is distinguished from scholastic theology, which assumes to establish the truth of the Christian doctrines by argument. John Damascenus was one of the first who wrote an exposition of Christian dogmatics. [DAMASCENUS, in BIOG. DIV.] But although the authority of the Scriptures and of the early fathers is acknowledged by all Christians, there are other authorities which are acknowledged only by one communion, and not by others. Thus the Greek church acknowledges the authority of the earlier councils only, while the Roman Catholics look upon the later councils and the bulls and decretals of the popes as equally positive authority in matters of faith; and the Protestant and reformed churches, rejecting the latter, recur to their respective synods and confessions of faith. Melancthon wrote a concise exposition of the dogmas of the Protestant or Lutheran church. Among the numerous Roman Catholic writers on dogmatic theology, Bellarmine is one of the most distinguished. Dogmatic theology, as distinct from scholastic as well as from moral theology and Biblical divinity, constitutes a separate chair in several Roman Catholic universities in continental Europe, and in those of Ireland.

In the Protestant universities of Germany there is a chair for the history of dogmas. The business of the professor is to examine the doctrines of the various sects which have divided Christianity, their sources, and the arguments by which they are supported. Such a course of lectures forms an important addition to the study of Ecclesiastical History.

DOIT or **DUYT**, a small Dutch copper coin, being the eighth part of a stiver, in value half a farthing. Doit is also a division of the English grain Troy. See Snelling's 'View of the Coins of Europe,' 8vo. London, 1766. The word is used by Shakspere, 'Coriolanus,' Act i., sc. 5.

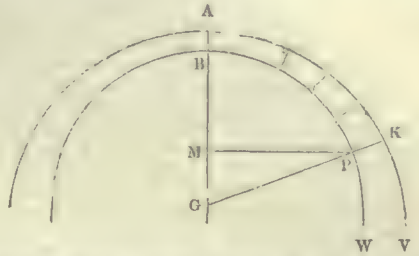
DOLLAR. [MONEY.]

DOME. The mathematical theory of a dome, so far as considerations requisite for security are concerned, is more simple than that of an arch. Imagine two vertical planes passing through the axis of a dome, and making a small angle with each other. These planes intercept (as in the cut) two symmetrically opposite slices of the dome, which tend to support each other at the crown. This support might be made complete and effectual upon principles explained in the article ARCH; so that in fact each small slice of the dome, with its opposite, might compose a balanced arch. Any slice of such a dome is supported by the opposite one only, so that all the rest might be taken away. Now suppose such a dome to be constructed upon an interior centering, of which however the arches are not separately balanced, in consequence of the weight of A P K being so great that the resultant of this weight and the horizontal thrust at A falls obliquely, not being, as in a balanced arch, perpendicular to PK, but cutting the line K P produced towards the axis. Still this dome cannot fall: for since every part of the horizontal course of stones has the same tendency to fall inwards, these pressures inwards cannot produce any effect, except a lateral pressure of each slice upon the two which are vertically contiguous. Hence the condition of equilibrium of a dome is simply this, that the weight of any portion A M P K must be too great for a balanced arch. Upon the same principle a dome may even be constructed with a concave exterior: and in a dome of convex exterior a portion of the crown may be removed, as is the case when the building is surmounted by a lantern. The tendency of the upper part to fall inwards being equal all round, each stone is supported by those adjacent.



From the preceding it appears that it would be (in comparison with an arch) easy to construct a dome with perfectly polished stones, and without cement. The friction of the stones and the tenacity of the cements are of course additional securities. The part in which the construction is weakest will be near the base, more particularly if the joints become nearly horizontal at the base, or if the circumference at the base be very considerable. This weak point is generally secured in practice by bringing strong chains or hoops round the horizontal courses at the interior of the base. Dr. Robison says, "The immense addition of strength which may be derived from hooping largely compensates for all defects; and there are hardly any bounds to the extent to which a very thin dome vaulting may be carried when it is hooped or framed in the direction of the horizontal courses." This system of internal hooping is every way preferable to reliance upon cements, and may, without interference with the ornamental part of the design, be carried to any length. Among other advantages, a dome may be made by means of it to rise vertically from the base, which cannot be the case in an arch.

The thickness of a dome should increase towards the base. A perfectly spherical dome, that is, a segment of a hollow shell cut off by a plane, and therefore of uniform thickness, will stand securely if the arch of the generating circle subtend at the centre less than 51° 49′. The law of the thickness necessary to secure equilibrium is as follows:—



Let the dome be formed by the revolution of A V and B W, and let P K, the joint of one of the stones, be always perpendicular to the interior curve; which is usually the case in practice. Let A M $= x$, M P$=y$, P K$=z$, arc B P$=s$; and let p be any constant *greater than unity*, and A any constant whatever. Then there will be equilibrium, the equation of B P W being given, if

$$z = \frac{Ap}{y}, \left(\frac{dx}{dy}\right)^{p-1} \cdot \frac{d}{ds}\frac{dx}{dy}$$

or e being the angle K G B, and ρ the radius of curvature at P

$$z = \frac{Ap\,(\tan e)^{p-1}}{py \cos^3 e}$$

For the demonstration of this formula, see Venturoli's 'Mechanics' (Creswell's translation), or Robison's 'Mechanical Philosophy.' It is not necessary that p should be a constant: a reference to the work first cited will show how to proceed on the supposition that it is a function of x greater than unity.

It is to be observed, however, that the mathematical theory of dome construction is utterly inapplicable to the extraordinary works of the Mohammedan architects, in which the curve of the dome itself is often carried considerably beyond the points of support. Evidently in such buildings as the Madrissa of Sultan Hussein at Ispahan, the Taj Mehal at Agra, or the tomb of Mahomet at Beejapore, given by Mr. Fergusson in his 'Handbook of Architecture,' the stability of the domes depends entirely upon the adhesion of the materials themselves; for if they had been free to move under the influence of gravity the domes must have fallen.

DOME (in Architecture). A term usually applied in England to express what more properly should be called a "cupola," or a spherical covering of a building or hall. The confusion in the use of this word seems to have arisen from the fact that the Italians and the Germans call the cathedrals, or principal churches of their towns by the generic name duomo, or dom, from the Greek Δωμα, as being *the* houses by way of distinction; and from the additional fact that the majority of the churches or cathedrals built in Italy since the revival of literature have been built with cupolas. It would now be impossible to bring the word back to its original signification, and it may therefore be considered that the term *dome* expresses generically the spherical or the spherico-polygonal coverings of buildings, whether the plans of those buildings be circular or not; that is to say whether the spherical coverings be raised over a rotunda, or over a drum carried down by pendantives to a square base. Specifically the term *dome* expresses the outer, or the convex, side of the covering; whilst that of *cupola* expresses the inner, or the concave side.

Neither the Assyrians, Egyptians, nor the Greeks appear to have resorted to domical construction, although there were some rude attempts occasionally made by the latter nation, as in the treasure chamber at Mycenæ, to carry out that mode of vaulting. The Etruscans seem to have been the first people who habitually employed the dome, and they very frequently adopted it in their tombs or their votive monuments. It was no doubt from them that the Romans derived this style of ornamentation; and it is certain that the most numerous ancient ruins of domes are to be found in the neighbourhood of Rome and Naples. The principal of these in and near Rome are the Pantheon and the temples of Bacchus, Vesta, Romulus, Hercules, Cybele, Neptune, and Venus, and also some of the chambers of the Thermæ.

The most magnificent dome of antiquity is unquestionably that of the Pantheon, supposed to be a chamber of the great baths of Agrippa. The diameter of the dome internally is 142 feet 8½ inches, with a circular opening at the top in the centre 28 feet 6 inches in diameter. The height of the dome from the top of the attic is 70 feet 8 inches. Internally it is decorated with five rows of square compartments. Each row is considerably larger than that immediately above it, as they converge towards the top. The large squares, all of which are rather more than 12 feet each way, contain four smaller squares sunk one within the other. It is supposed that these squares were decorated with plates of silver, from some fragments of that metal having been found on them. The opening at the top of the dome was decorated with an ornamented bronze moulding, gilt. The external part of the dome appears also to have been decorated with bands of bronze. Constantius II. removed the silver and bronze with which the building was decorated. The base of the dome externally consists of a large plinth with six smaller plinths or steps above it; and in the curve of the dome a flight of steps is formed which leads to the opening at the top of the dome. From the drawings of the architect Serlio it appears that flights of steps were formed at intervals all round the dome, which are now covered with the lead placed there by order of Urban VIII. The dome is constructed of bricks and rubble. Sunk bands round the hollow squares or caissons appear to be formed in brick, and the other parts in tufo and pumice stone. The thickness of the dome of the Pantheon is about 17 feet at the base, 5 feet 1½ inches at the top of the highest step, and 4 feet 7 inches at the top of the dome. The circular wall which supports the dome is 20 feet thick. This wall is however divided by several large openings, and is furnished with discharging arches of brick. It is most probable that the dome of the Pantheon was executed by means of a centering of wood with the hollow squares formed in relief upon it, as was afterwards done in constructing the great vaulting of St. Peter's.

The dome of one of the chambers of the Thermæ of Caracalla was 111 feet in diameter. In the Thermæ of Titus there are two domes each 84 feet in diameter, and in the baths of Constantine there was one of 76 feet. There were three domes in the baths of Diocletian, of which two still remain; one is 73 feet 6 inches in diameter, and the other 62 feet 3 inches. Judging from those that remain, there is every reason to believe that in the Thermæ they were all lighted from above, like the dome of the Pantheon. Near Pozzuoli there is a very perfect circular building, with a dome 96 feet in diameter, built of volcanic tufo and pumice stone. The temple of Minerva Medica, without the walls of Rome, was on the plan of a polygonal dome of ten sides built of brick and pumice stone. This building does not appear to have had any opening at the top.

The ancients appear to have constructed domes on corbels. At Catania there is a spherical dome which covers a square vestibule; and in one of the octagonal rooms of the enclosure surrounding the baths of Caracalla the corbels still remain which most probably supported the dome of the chamber.

The dome of Santa Sophia, at Constantinople, built in the reign of Justinian, is the most remarkable and the earliest constructed after those of the Romans. Anthemius of Tralles and Isidorus of Miletus were the architects. The present dome, however, was reconstructed by the nephew of Isidorus. It rests on the square formed at the intersection of the arms of the Greek cross: the diameter is about 111 feet, and the dome 40 feet high. The dome is supported by four corbellings placed in the angles of the square. The corbels are surmounted by a kind of cornice which supports a circular gallery. The lower part of the dome is pierced with a row of small windows adorned with columns on the exterior. Externally the dome is divided by projecting ribs, rounded and covered with lead. The top is surmounted by a lantern or finishing like a baluster, on which is a cross. The dome of Anthemius and Isidorus was not so high, and was partly destroyed twenty-one years after its construction by an earthquake during the lifetime of Justinian. In the reconstruction the nephew of Anthemius used very light white bricks, only one fifth the weight of common bricks, which are said to have been made in Rhodes. It appears from the history and description of the building of Santa Sophia, by Procopius, that the architects encountered many difficulties, which arose probably from not being thoroughly acquainted with the principles on which domes should be constructed. (Procopius, *περὶ κτισμάτων*, lib. i. cap. 1.)

The dome of San. Vitale, at Ravenna, which is considered to be more ancient than that of Santa Sophia, is curiously constructed. The lower part of the plan of the dome is a regular octagon, which is supported by eight piers placed at the angles of the dome. Between these angles are seven tall niches divided into two stories. The lower part of these niches is open, and ornamented with columns, like Santa Sophia. The eighth side of the dome is pierced with a great arch forming an entrance. This arch is of the same diameter and the same elevation as the niches. The wall above the niches and arch, which is without openings, sustains a hemispherical dome, the plan being a circle described within a regular octagon. Corbels are not employed as at Santa Sophia, but the arches support the gathering over, or corbelling, which forms the circular base of the dome. The base of the dome is pierced with eight windows, each divided in the middle by a column which supports two small arches. The dome itself is built with a double row of pipes, hollow at one end and pointed at the other, the point of one being placed in the hollow of the preceding. They are thus continued in a gentle spiral line until they finish at the top. Between the top of the small arched windows and the pipes there is a construction formed with vases, not unlike the system adopted in the circus of Caracalla. The dome itself is covered with mortar both within and without.

The church of San Marco at Venice, built in the 10th century, by order of Pietro Orseolo, the then doge, is decorated with five domes. One of these, placed in the centre of the church, is much larger than the others. Each dome is enclosed within four pieces of semi-cylindrical vaulting, together forming a square, in the angles of which are four corbels, which gather in the circular base of each dome. The lower part of the dome is pierced with small windows. The interior is covered with mosaic, and the top of the dome is terminated with a finishing on which is a cross. In 1523 the doge, Andrea Gritti, caused the domes to be repaired, and Sansovino, the architect, restored in a great measure the supports, and placed (at about one-third of its height) a great circle of iron round the large dome to prevent its falling; a precaution which has been completely successful. The other domes are not so well preserved. In 1729 one of the smaller domes was in danger of falling, from the decay which had taken place in a circular bond placed at the base of the dome. Stone was however substituted for the wooden bond, and a circle of iron placed without the dome near its base. In 1735 Andrew Tirali, the architect to the church, placed an iron circle round the dome which is near the great gate, on account of some small fractures which were then perceived. If, however, the other domes are constructed with a wooden bond, it is very probable that they will eventually fall unless steps be taken in time to remove the timber. By the use however of corrosive sublimate, now used in Kyan's patent for preserving wood from the dry rot, wood may be used in the construction of domes with much more security as regards durability.

The celebrated dome of Santa Maria del Fiore, built by Bruneleschi, is far superior in construction to the domes of Santa Sophia and San Marco. Bruneleschi first constructed the octagon tower which supports the dome. Each face of the tower is pierced with a circular window; the walls are 17 feet thick, and the cornice which terminates the tower is 175 feet from the ground. From this cornice rises the double dome. The outer dome is 7 feet 10 inches thick at the base. The internal dome, which is connected at the angles with the external dome, is 139 feet in diameter and 133 feet high from the top of the internal cornice of the tower to the eye of the lantern. This dome has eight angles, forming a species of Gothic vault, and was the first double dome with which we are acquainted. Some time after the dome was finished, several fractures were perceived in it, which were owing to settlements in the masonry; but the fractures were filled up and no new signs of settlement have showed themselves since.

The first modern dome constructed in Rome was that of the Church of Our Lady of Loretto. It was commenced in 1507 by Antonio Sangallo. The dome, which is double, is circular on the plan. The internal dome is constructed on double consoles, instead of corbellings. The double consoles are crowned with a small cornice, forming an impost for eight arches, from the upper part of which springs the dome. On the top is a lantern light, which is not apparent externally.

Up to this time domes had been constructed on walls and corbellings; but in St. Peter's at Rome a new plan was adopted. The dome of St. Peter's stands upon four piers, 61 feet 11 inches high, and 30 feet 10 inches thick, measured in a straight line with the arches. From the arches spring the corbellings, which are finished by an entablature. Upon this entablature is a plinth. The plinth is externally an octagon, and internally a circle. The external diameter of the octagon is 192 feet 9 inches, and the internal circle 134 feet 8½ inches; the thinnest part of the wall, between the octagon and the circle, is 29 feet 8 inches. On the plinth is a circular stylobate, 28 feet 6½ inches thick. This thickness is divided into three parts by a circular passage, 5 feet 10 inches wide: the two walls on each side of this passage are, respectively, the internal wall 14 feet 7½ inches thick, and the external 8 feet. In the internal wall are other smaller passages, 2 feet 10 inches wide, forming flights of steps communicating with the four spiral staircases formed in the thickness of the wall of the drum of the dome. Above the circular stylobate, which is 12 feet 4½ inches high, is placed the drum of the dome, which is 10 feet 1½ inches thick, measured to the inside line of the pilasters, which decorate the interior of the dome. The pilasters themselves are 1·78 feet thick in addition. The construction is formed of rubble and fragments of brick. The interior is lined with bricks stuccoed. Externally the work is faced with thin slabs of travertine stone. The drum is pierced with sixteen windows, 9 feet 3¾ inches wide and 17 feet high. The walls are strengthened on the outside, between the windows, with sixteen buttresses, constructed with solid masonary. These buttresses are 13 feet 3 inches wide and 51 feet 6 inches in height, from the base to the top of the entablature. Each buttress is decorated and strengthened with half pilasters, and terminates with two coupled columns engaged, the diameter of which is 4 feet: the order is Corinthian. When the base of the dome had been built to the height of the entablature of the drum, Michel Angelo died: but some time before his death he had caused a wooden model to be made, with ample details, to which he added drawings and instructions. After his death Pirro Ligorio and Vignola were appointed the architects. Giacomo della Porta, the pupil of Vignola, followed his master as architect to the cathedral; but though the designs of Michel Angelo were strictly followed, the dome itself was constructed under the pontificate of Sixtus V. Sixtus gave Giacomo della Porta as a colleague Domenico Fontana, by whom the dome was constructed.

On the constructions of Michel Angelo a circular attic was first formed, 19 feet 2¼ inches high, and 9 feet 7 inches thick. This attic is strengthened externally by 16 projections, 2 feet 11 inches deep, and 6 feet 4½ inches wide, placed over the buttresses of the dome. On the attic rises the double dome, the internal diameter of which, at the base, is 138 feet 5 inches. The curve externally is an arc of a circle whose radius is 84 feet 1·62 inches. To the height of 27 feet 8 inches from the attic the dome is solid. At the base the thickness is 9 feet 7 inches; and as the external dome is raised higher than the internal dome, the thickness is increased as the curve ascends, so that where the dome is divided the thickness is 11 feet 4 inches. The circular space which divides the two domes is 3 feet 2¼ inches wide; the internal dome is 6 feet 4 inches thick; and the height from the attic to the opening of the lantern is 83 feet 10 inches. The diameter of the lantern is 24 feet 10 inches. The external dome is 2 feet 10½ inches thick where it separates itself from the internal dome; and it is strengthened externally by 16 projecting bands of the same thickness. The dome is pierced with three rows of small windows. As the curves of the dome are not concentric, the space between them becomes wider as it rises; so that at the opening of the lantern the space is 10 feet wide. These domes are joined together by 16 walls or spurs, diminishing in thickness as they ascend to the lantern; at the base they are 8 feet thick, and at the summit 3 feet. The base of the lantern is arched, and pierced with small windows. Above the two domes is a circular platform, surrounded with an iron gallery. In the centre rises the lantern, on a stylobate broken into 16 parts, forming projecting pedestals, above which are buttresses similar to the buttresses of the drum, decorated externally with coupled Ionic columns, 17¼ inches in diameter. The space between the buttresses is filled with arched openings, which give light to the lantern. The external diameter of the lantern is 39 feet; the internal diameter 25 feet 11 inches; and the height from the platform to the top of the cross is 89 feet 7½ inches. The whole height, from the external plinth of the dome to the cross, is 263 feet. The total height from the pavement is 437 feet 5 inches. The total height internally, to the top of the dome of the lantern, is 387 feet.

Sixtus V. covered the external dome with lead, and the bands with bronze gilt. One hundred thousand large pieces of wood were used in making the centering of the domes, which was so admirably constructed that it appeared suspended in the air. (See the drawings in the work by Fontana, on the construction of this dome.) This centering was more for the purpose of a scaffolding for the materials and workmen, than to sustain the weight of the double dome. During the construction of the dome it is believed that only two circles of iron were placed round the masonry, one of which was placed on the outside of the internal dome, at about 36 feet from its springing, and one foot above the division of the domes. The bands of iron of which this circle is composed are 3 inches wide by 1¾ inch thick. A similar circle is placed about the middle of the solid part of the dome, at about 17 feet 6 inches above the springing of the internal dome. Near the top of the internal dome there are several holes, at the bottom of which upright iron bars appear. These bars are said to be the connecting rods which keep together other circles of iron placed at different heights within the masonry, which are finally terminated by a circle round the eye of the dome.

The domes were constructed with such haste, that sufficient time was not allowed to the work to take a solid bed as it was carried up, in consequence of which a great number of vertical settlements have occurred, and the circle of iron round the internal dome was fractured. To obviate the danger arising from these settlements, six circles of iron were placed round the external dome at different heights, and the broken circle of the internal dome was repaired. The first circle was placed above the cornice of the external stylobate, or continuous plinth, on which the buttresses stand; the second circle was placed above the cornice of the buttresses, the third above the attic at the springing of the external dome, the fourth half way up the external dome, and the fifth under the base of the lantern. A sixth was shortly after placed at one foot below where the dome divides itself. The iron bands are flat, from 16 to 17 feet long, 3¼ inches wide, and 2¼ inches thick. At one end of the pieces of iron a hole is made; the other end is turned up and passed through the eye of the next band. The whole of these bands are fixed with iron wedges, driven into the rubble with mallets. Sheets of lead are placed under the iron circles. In the 'Encyclopédie Méthodique' there is a detailed account of the various fractures of the dome, and the means employed to repair them. ('Encyclopédie Méthodique,'—Architecture, article Coupole.)

The dome of St. Paul's Cathedral, London, is placed over the intersection of the arms of the cross. The ground plan is a regular octagon, each face of which is 44 feet 8¾ inches wide; four of these sides are formed by the four great arches of the naves; the other four sides are formed by false arches of the same size; in each of these arches there is a great niche, the base of which is pierced with two arches. By this

ENGLISH FEET.

Parallel Section of the four principal Domes of Europe, to the same scale; by Joseph Gwilt.

means eight supports are obtained instead of four, and the corbellings do not project too much, as in other similar constructions. The corbellings gather in a circle, the diameter of which is 104 feet 4 inches, the octagon base being 107 feet. The corbellings are surmounted by a complete entablature, 8 feet 3 inches high, decorated with consoles. The drum is set back 3 feet 2½ inches from the face of the frieze, and this intermediate space is occupied by two steps and a seat. The cornice is 95 feet 9¾ inches from the pavement. The height of the drum from the top of the seat is 62 feet 6½ inches to the springing of the internal dome. The wall forming the drum is inclined internally 4 feet 11¼ inches, or about the 12th part of its height. This was designed by the architect to increase the resistance of the walls to the united pressure of the large internal vault and the conical dome which carries the lantern.

The interior of the drum is decorated with a continuous stylobate, on which is an order of Corinthian pilasters. The 32 spaces between the pilasters are filled with 24 windows and 8 large niches. Externally the drum is decorated with an order of 32 Corinthian columns engaged, which are united to the wall of the drum by eight solid constructions in masonry. In each space between the constructions there are three intercolumniations, the columns being joined at their bases by walls pierced with arches. The external colonnade is surmounted by an entablature, with a mutuled cornice, on which is a balustrade; behind this is a terrace, formed by the recessing back. The attic is 22 feet 4¼ inches high from the top of the balustrade to the under side of the cornice of the attic. Above the internal order of the drum rises the interior dome, the diameter of which at the springing is 102 feet 2¾ inches by 51 feet in height. The top of the dome has a circular opening 14 feet 10¾ inches in diameter.

Above the attic are two steps, from which the external dome springs. The external dome is constructed of wood, covered with lead, and decorated with projecting ribs forming panels, curved at the ends. This dome terminates with a finishing which joins the base of the lantern; the circular gallery formed on the finishing is 274 feet 9 inches above the pavement of the nave. The lantern is supported on a conical tower, terminated by a spherical dome. This tower, which is joined to the internal dome at its base, disengages itself from it at the height of 8 feet 6 inches above the springing of the same. The perpendicular height of this tower is 86 feet 9 inches, and the walls are inclined 24 degrees from the perpendicular. The diameter of the base is 100 feet 1 inch measured externally, and 34 feet 1 inch at the springing of the spherical dome which finishes it. The wall of this tower is built of brick, and is 1 foot 7 inches thick, with circular rings of masonry, fastened with iron bands. The spherical dome at the top of the tower has an opening 8 feet in diameter at the summit. Between the attic and the wall of the tower are 32 walls or buttresses, which also serve to bear the ribs of the wooden external dome.

About the same time that Wren built the dome of St. Paul's, Hardouin Mansard, a French architect, constructed the dome of the Invalides at Paris. The plan of this dome is a square, in which is inscribed a Greek cross; in the angles of the square there are four chapels. The dome is raised in the centre of the Greek cross; the base supporting it is an octagonal figure, with four large and four small sides. The four small sides form the faces of the piers of the dome; the large sides are the arched openings of the nave and transverse aisles. A circular entablature is placed over the corbellings, and on the entablature is raised the drum of the dome, the diameter of which is 79 feet 9½ inches. The interior of the drum is decorated with a continuous stylobate, above which are coupled pilasters of the composite order, and the wall is pierced with 12 windows. The dome, which is double, rises from a spinging common to both. The lower or internal dome, constructed with masonry, is spherical, and is 83 feet in diameter, with an opening or eye at the top 53 feet 3 inches in diameter, through which part of the outer dome can be seen. The outer dome is of a spheroidal form, and constructed of stone at the base and of brick above. Externally the dome is formed with a stylobate, on which is a Corinthian order of columns, over which is an attic with pilasters, and buttresses in the form of consoles. The drum is fortified externally by eight projections, placed two and two above each pier of the dome. The external dome is framed of wood and covered with lead, like St. Paul's, London, but the construction is much heavier. The external diameter of the dome is 85 feet 4 inches, and its height is 57 feet 2½ inches. The finishing of the dome is decorated with consoles, on which is formed a circular balcony round the base of the lantern, constructed of wood, which is 39 feet 4¾ inches high; the lantern above it, with the cross, is 35 feet 4¾ inches high. The total height from the ground is 330 feet.

The dome of the Pantheon at Paris is constructed entirely of stone, and is placed in the centre of a Greek cross. It is supported by four triangular piers strengthened by engaged columns of the Corinthian order. The four piers with the lines of the intermediate arches form externally a large square, each side of which is 74 feet 9 inches.

These four piers are pierced above with arched openings, and between the piers with the openings are large arches, the diameter of which is 44 feet 11½ inches, and the height 85 feet 5 inches. Between these arches rise the corbellings, which are gathered in to form the circular plan of the drum. The arches and the corbellings are crowned with a large entablature 13 feet 4 inches high. The upper part of the cornice of the entablature is raised 101 feet above the pavement of the nave. The diameter taken at the frieze is 66 feet. The internal drum which is constructed on this entablature is 55 feet 7½ inches in height to the springing of the internal dome. The interior of this drum is decorated with a continuous stylobate, which is the basement of a colonnade of 16 Corinthian columns almost isolated from the wall. These columns are 35 feet 2¾ inches in height. Between the columns are 16 windows, four of which are false, and placed above the four piers of the dome. The colonnade is crowned with an entablature, above which is a large plinth which rises to the springing of the internal dome. The internal dome is 66 feet 8½ inches in diameter at the springing, and is decorated with octagonal caissons or sinkings with a rose in the centre of each. The eye at the top of the dome is 31 feet 3¼ inches in diameter. Through this eye is seen the upper part of another or intermediate dome. The external dome is placed on a circular base 108 feet 7¼ inches in diameter and square at the bottom. The angles are strengthened by flying buttresses. Above the corbellings a circular wall is constructed, forming an external continuous stylobate which supports an external colonnade. The external colonnade constructed on the stylobate forms a peristyle round the dome, and is composed of 32 isolated columns of the Corinthian order 36 feet 5¾ inches high. This colonnade is divided into four parts by the solid constructions in masonry raised over the four piers. The external colonnade is surmounted with an entablature and balustrade above it. There is an attic constructed above the circular wall of the drum, set back 13 feet 10 inches, and pierced with 16 windows, 12 of which light the space between the internal dome and the intermediate dome which bears the lantern. This attic is terminated with a cornice with a step or plinth above. The external dome, 77 feet 8¾ inches in diameter, measured on the outside, is constructed with masonry; the height is 45 feet 9½ inches from the top of the attic to the underside of the finishing against which the curve terminates. The outside of the dome is covered with lead, and is equally divided vertically by 16 projecting ribs. The intermediate dome, built for the purpose of carrying the lantern, was intended to be decorated with subjects by the painter, and we believe it has since been decorated. The form of this dome resembles the small end of an egg: its springing commences at the base of the attic at the point where the internal dome begins to disengage itself. This dome is 50 feet ¾ inch high, and 70 feet 3½ inches in diameter, and is pierced with four great openings at the lower part 37 feet 8 inches high, and 30 feet 10½ inches wide at the base. On a circular platform above the summit of the dome are eight piers with arches, which support the finishing against which the external dome terminates. Above this is the lantern of the dome.

Very full details of the most remarkable domes in Europe are given in the 'Encyclopédie Méthodique' (article Architecture), from which this brief notice is in a great measure taken. For an account of the construction of wooden-ribbed domes, see Nicholson's 'Architectural Dictionary;' also the section of the Pantheon dome by Taylor and Cressy; also the work on St. Peter's, by Fontana. The dome of the Reading Room of the British Museum is described in the article BRITISH MUSEUM.

The following admeasurements of most of the principal domes of Europe are chiefly from Mr. Ware's 'Tracts on Vaults and Bridges':—

(Isabelle, *Edifices Circulaires*; Rondelet, *L'Art de Batir*; Fergusson, *Handbook of Architecture.*)

DOMESDAY BOOK, the register of the lands of England, framed by order of King William the Conqueror. It was sometimes termed 'Rotulus Wintoniæ,' and was the book from which judgment was to be given upon the value, tenures, and services of the lands therein described. The original is comprised in two volumes—one a large folio, the other a quarto. The first begins with Kent, and proceeds with other counties in the following order: Sussex, Surrey, Hampshire, Berkshire, Wiltshire, Dorsetshire, Somersetshire, Devonshire, Cornwall, Middlesex, Hertfordshire, Buckinghamshire, Oxfordshire, Gloucestershire, Worcestershire, Herefordshire, Cambridgeshire, Huntingdonshire, Bedfordshire, Northamptonshire, Leicestershire, Warwickshire, Staffordshire, Shropshire, Cheshire, Derbyshire, Nottinghamshire, Yorkshire, and concluding with Lincolnshire. It is written on 382 double pages of vellum, in one and the same hand, in a small but plain character, each page having a double column; it contains 31 counties. After Lincolnshire (fol. 373), the claims arising in the three ridings in Yorkshire are taken notice of, and settled; then follow the claims in Lincolnshire, and the determinations of the jury upon them (fol. 375); lastly, from fol. 379 to the end there is a recapitulation of every wapentake or hundred in the three ridings of Yorkshire, of the towns in each hundred, what number of carucates and oxgangs are in every town, and the names of the owners placed in a very small character above them. The second volume, in quarto, is written upon 450 double pages of vellum, but in a single column, and in a large fair character, and contains the counties of Essex, Norfolk, and Suffolk. In these counties the "liberi homines" are ranked separate; and there is also a title of "Invasiones super Regem."

These two volumes are preserved, among other records of the Exchequer, in the Chapter House at Westminster; and at the end of the second is the following memorial in capital letters of the time of its completion: "Anno Millesimo Octogesimo Sexto ab Incarnatione Domini, vigesimo vero regni Willielmi, facta est itsa Descriptio, non solum per hos tres Comitatus, sed etiam per alios." From internal evidence, there can be no doubt but that the same year, 1086, is assignable as the date of the first volume.

In 1767, in consequence of an address of the House of Lords, George III. gave directions for the publication of this survey. It was not, however, till after 1770 that the work was actually commenced. Its publication was entrusted to Mr. Abraham Farley, a gentleman of learning as well as of great experience in records, who had almost daily recourse to the book for more than forty years. It was completed early in 1783, having been ten years in passing through the press, and thus became generally accessible to the antiquary and topographer. It was printed in fac-simile, as far as regular types, assisted by the representation of particular contractions, could imitate the original.

In 1816 the commissioners upon the public records published two volumes supplementary to Domesday, which now form one set with the volumes of the Record. One of these contains a general introduction, accompanied with two different indexes of the names of places, an alphabetical index of the tenants in capite, and an 'Index Rerum.' The other contains four records: three of them, namely, the Exon Domesday, the Inquisitio Eliensis, and the Liber Winton., contemporary with the Survey; the other record, called 'Boldon Book,' is the survey of Durham, made in 1183, by Bishop Hugh Pudsey. These supplementary volumes were published under the superintendence of Sir Henry Ellis.

Northumberland, Cumberland, Westmoreland, and Durham were not included in the counties described in the Great Domesday; nor does Lancashire appear under its proper name; but Furness, and the northern part of that county, as well as the south of Westmoreland and part of Cumberland, are included within the West Riding of Yorkshire. That part of Lancashire which lies between the rivers Ribble and Mersey, and which at the time of the survey comprehended 6 hundreds and 188 manors, is subjoined to Cheshire. Part of Rutlandshire is described in the counties of Northampton and Lincoln; and the two ancient hundreds of Atiscross and Existan, deemed a part of Cheshire in the survey, have been since transferred to the counties of Flint and Denbigh. In the account of Gloucestershire we find a considerable portion of Monmouthshire included, seemingly all between the rivers Wye and Usk. Kelham thinks it probable that the king's commissioners might find it impossible to take any exact survey of the three counties northernmost of all, as they had suffered so much from the Conqueror's vengeance. As to Durham, he adds, all the country between the Tees and Tyne had been conferred by Alfred on the bishop of this see; and at the coming in of the Conqueror he was reputed a count-palatine.

The order generally observed in writing the Survey was to set down in the first place at the head of every county (except Chester and Rutland) the king's name, *Rex Willielmus*, and then a list of the bishops, religious houses, churches, any great men, according to their rank, who held of the king in capite in that county, likewise of his thains, ministers, and servants; with a numerical figure in red ink before them, for the better finding them in the book. In some counties the cities and capital boroughs are taken notice of before the list of the great tenants is entered, with the particular laws or customs which prevailed in each of them; and in others they are inserted promiscuously. After the list of the tenants, the manors and possessions themselves which belong to the king, and also to each owner throughout the whole county, whether they lie in the same or different hundreds, are collected together and minutely noted, with their under-tenants. The king's demesnes, under the title of *Terra Regis*, always stand first.

For the adjustment of this survey certain commissioners, called the king's justiciaries, were appointed. In folios 164 and 181 of the first volume we find them designated as "Legati Regis." Those, for the midland counties at least, if not for all the districts, were Remigius, bishop of Lincoln, Walter Giffard, earl of Buckingham, Henry de Ferrers, and Adam, the brother of Eudo Dapifer, who probably associated with them some principal person in each shire. These inquisitors, upon the oaths of the sheriffs, the lords of each manor, the presbyters of every church, the reves of every hundred, the bailiffs and six villains of every village, were to inquire into the name of the place, who held it in the time of king Edward, who was the present possessor, how many hides in the manor, how many carucates in demesne, how many homagers, how many villains, how many cotarii, how many servi, what free-men, how many tenants in socage, what quantity of wood, how much meadow and pasture, what mills and fish-ponds, how much added or taken away, what the gross value in king Edward's time, what the present value, and how much each free-man or soc-man had or has. All this was to be triply estimated: first, as the estate was held in the time of the Confessor; then as it was bestowed by king William; and thirdly, as its value stood at the formation of the survey. The jurors were, moreover, to state whether any advance could be made in the value. Such are the exact terms of one of the inquisitions for the formation of this survey, still preserved in a register of the monastery of Ely.

The writer of that part of the Saxon Chronicle which relates to the Conqueror's time, informs us with some degree of asperity, that not a hide or yardland, not an ox, cow, or hog, was omitted in the census. It should seem, however, that the jurors, in numerous instances, framed returns of a more extensive nature than were absolutely required by the king's precept, and it is perhaps on this account that we have different kinds of descriptions in different counties.

It is not necessary to go more minutely into the contents of this extraordinary record, to enlarge upon the classes of tenantry enumerated in it, the descriptions of land and other property therewith connected, the computations of money, the territorial jurisdictions and franchises, the tenures and services, the criminal and civil jurisdictions, the ecclesiastical matters, the historical and other particular events alluded to, or the illustrations of ancient manners, with information relating to all of which it abounds, exclusive of its particular and more immediate interest in the localities of the country for the county historian.

As an abstract of population it fails. The tenants in capite, including ecclesiastical corporations, amounted scarcely to 1400; the under-tenants to somewhat less than 8000. The total population, as far as it is given in the record itself, amounts to no more than 282,242 persons. In Middlesex, pannage (payment for feeding) is returned for 16,535, in Hertfordshire for 30,705, and in Essex for 92,991 hogs; yet not a single swine-herd (a character so well known in the Saxon times) is entered in these counties. In the Norman period, as can be proved from records, the whole of Essex was, in a manner, one continued forest; yet once only in that county is a forester mentioned, in the entry concerning Writtle. Salt-works, works for the production of lead and iron, mills, vineyards, fisheries, trade, and the manual arts, must have given occupation to thousands who are unrecorded in the survey; to say nothing of those who tended the flocks and herds, the returns of which so greatly enlarge the pages of the second volume. In some counties we have no mention of a single priest, even where churches are found; and scarcely any inmate of a monastery is recorded beyond the abbot or abbess, who stands as a tenant in capite. These remarks might be extended, but they are sufficient for their purpose. They show that, in this point of view, the Domesday Survey is but a partial register. It was not intended to be a record of population further than was required for ascertaining the geld.

There is one important fact, however, to be gathered from its entries. It shows in detail how long a time elapsed before England recovered from the violence attendant on the Norman Conquest. The annual value of property, it will be found, was much lessened as compared with the produce of estates in the time of Edward the Confessor. In general, at the Survey, the king's lands were more highly rated than before the Conquest; and his rent from the burghs was greatly increased; a few also of the larger tenants in capite had improved their estates; but, on the whole, the rental of the kingdom was reduced, and twenty years after the Conquest the estates were, on an average, valued at little more than three-fourths of the former estimate. An instance appears in the county of Middlesex, where no Terra Regis however occurs. The first column, headed T.R.E., shows the value of the estates in the time of King Edward the Confessor;

the second, the sums at which they were rated at the time of the Survey, *tempore Regis Wilhelmi.*

We shall now say a few words on the uses and consequences of the Survey. By its completion the king acquired an exact knowledge of the possessions of the crown. It afforded him the names of the landholders. It furnished him with the means of ascertaining the military strength of the country; and it pointed out the possibility of increasing the revenue in some cases, and of lessening the demands of the tax-collectors in others. It was moreover a register of appeal for those whose titles to their property might be disputed.

Appeals to the decision of this Survey occur at a very early period. Peter of Blois notices an appeal of the monks of Croyland to it in the reign of Henry I. Others occur in the Abbreviatio Placitorum from the time of John downward. In later reigns the pleadings upon ancient demesne are extremely numerous: and the proof of ancient demesne still rests with the Domesday Survey. Other cases in which its evidence is yet appealed to in our courts of law, are in proving the antiquity of mills, and in setting up prescriptions *in non decimando.* By stat. 9 Edw. II., called Articuli Cleri, it was determined that prohibition should not lie upon demand of tithe for a new mill. The mill, therefore, which is found in Domesday must be presumed older than the 9th Edw. II., and is, of course, discharged, by its evidence, from tithe.

On the discharge of abbey-lands from tithes, as proved by Domesday, it may be proper to state that Pope Paschal II. at an early period, exempted generally all the religious from paying tithes of lands in their own hands. This privilege was afterwards restrained to the four favoured Orders, the Cistercians, the Templars, the Hospitallers, and the Premonstratensians. So it continued till the fourth Council of Lateran in 1215, when the privilege was again restrained to such lands as the abbeys had at that time, and was declared not to extend to any after-purchased lands. And it extends only to lands *dum propriis manibus coluntur.* From the paucity of dates in early documents, the Domesday Survey is very frequently the only evidence which can be adduced that the lands claiming a discharge were vested in the monastery previous to the year expressed in the Lateran Council.

Although in early times, Domesday, precious as it was always deemed, occasionally travelled, like other records, to distant parts, till 1696 it was usually kept with the king's seal, at Westminster, by the side of the Tally Court in the exchequer, under three locks and keys, in the charge of the auditor, the chamberlains, and the deputy-chamberlains of the exchequer. In the last-mentioned year it was deposited among other valuable records in the Chapter-house, where it still remains.

The two most important works for the student of the Domesday Survey are Kelham's 'Domesday Book illustrated,' 8vo, Lond. 1788, and the 'General Introduction' to the survey, reprinted by command of his Majesty under the direction of the commissioners on the Public Records, 2 vols., 8vo, 1833, accompanied by fresh indices. A translation of the whole, under the title of 'Dom-Boc,' was undertaken early in the present century by the Rev. William Bawdwen, vicar of Hooton Pagnell, in Yorkshire, who published Yorkshire, with the counties of Derby, Nottingham, Rutland, and Lincoln, in 4to, Doncaster, 1809, followed by the counties of Middlesex, Hertford, Buckingham, Oxford, and Gloucester, 4to, Doncaster, 1812; but the work went no further. County portions of this record will be found translated in most of our provincial histories; the best are undoubtedly those in Dugdale's Warwickshire, Nichols's Leicestershire, Hutchins's Dorsetshire, Nash's Worcestershire, Bray and Manning's Surrey, Clutterbuck's Hertfordshire, Surtees' Durham, Ormerod's Cheshire, and Baker's Northamptonshire, as far as it was published. Mr. Henry Penruddocke Wyndham published Wiltshire, extracted from Domesday Book, 8vo, Salisb. 1788, and the Rev. Richard Warner, Hampshire, 4to, Lond. 1789. Warwickshire has been published more recently by Mr. Reader. There are numerous other publications incidentally illustrative of Domesday topography, which the reader must seek for according to the county as to which he may desire information.

DOMICILE. In the Roman law *Domicilium.* Many jurists have attempted to define domicile, but they have scarcely succeeded in so doing; the question, whether one domicile has been abandoned and another acquired depends so much upon acts and intention in each particular case, that no general rule will universally apply. A domicile might be described as "a residence at a particular place, with an evident intention to remain there."

The following rules appear to comprise the generally adopted principles on the subject:—

1. The domicile of the parents is the domicile of the child. "*Patris originem unusquisque sequitur.*" ('Cod.' lib. 10, tit. 32 (31), 36.) This is usually called the domicile of origin or nativity, and is in most cases the same with the place of birth. But the mere accident of birth in a place where the parents may happen to be *in itinere*, or on a visit, will have no effect in determining the domicile of origin. An illegitimate child, having no father in contemplation of law, follows the domicile of its mother.

2. Minors are generally considered incapable of changing, by their own act, the domicile of origin during their minority. If the father change his domicile, that of the children follows it; and if he dies, his last domicile will be that of his infant children. It has been much questioned whether the guardians of minors, idiots, or lunatics can change their domicile. It has been held in England that a mother, being guardian, might change the domicile of her children, provided it was not done for a fraudulent purpose, which would be presumed in the absence of any reasonable motive. In Scotland, a minor, after the age of puberty, is not personally under the control of his guardian, and may change his domicile by his own act.

3. A married woman follows the domicile of her husband.

4. A widow retains the domicile of her late husband till she acquires another.

5. The place where a man resides is, for a great many purposes, to be considered his domicile, and, *primâ facie,* is to be taken to be so till other facts establish the contrary.

6. Every person of full age, who removes from one place to another, with the intention of making the latter his place of permanent residence, constitutes it his domicile.

7. The domicile of origin must be considered to prevail till the party has not only acquired another, but manifested and carried into effect an intention of abandoning his former domicile, and adopting another as his sole domicile. But the domicile of origin cannot be preserved by a mere floating intention of returning to it at some future period, or revived by a mere abandonment of the acquired domicile, unless perhaps where the party dies *in itinere* towards the intended domicile. "It is to be remembered," says Sir William Scott (Lord Stowell), "that the native character easily reverts, and that it requires fewer circumstances to constitute domicile in the case of a native subject than to impress the national character on one who is originally of another country."

8. An acquired domicile is not lost by mere abandonment, but continues until a subsequent domicile is acquired, which can be done only *animo et facto.*

9. A married man's domicile is generally taken to be where the residence of his family is; unless this conclusion is controlled by circumstances, such as proof that he has altogether abandoned his family, or that their place of residence is temporary: but

10. If a man, whether married or not, has two places of residence at different times of the year, that will be esteemed his domicile which he himself selects, describes, or deems to be his home, or which appears to be the centre of his affairs; for example, that of a nobleman or country gentleman, his residence in the country—that of a merchant, his residence in town.

11. Residence in a place, to produce a change of domicile, must be voluntary. Thus, if it be produced by constraint, as by banishment, arrest, or imprisonment, it cannot affect the domicile. For the same reason a person abroad in the service of the state does not change his domicile. But it has been held that a Scotchman entering the service of the East India Company acquires a domicile in India, which (like a domicile acquired in any of the colonies) is in legal effect the same as a domicile in England. (Craigie *v.* Lewin, 3 Curt. Eccl. Rep. 447.)

12. It was held in the Roman law that a man might, under certain circumstances, be said to have no domicile, as when he quits one place of residence with the intention of fixing himself in another. But this is not admitted in our law, in which, as before stated, it is held that the former domicile is not lost till the new one is acquired *animo et facto.* And in the possible case of a man of unknown origin acquiring two contemporaneous domiciles under the same circumstances, the *lex loci rei sitæ* would probably prevail *ex necessitate* in questions as to his personal property.

Thus it appears that domicile, considered in relation to the civil status of the person, is of three kinds—1st, domicile of origin, depending on that of the parents at the time of birth; 2nd, domicile of choice, which is voluntarily acquired by the party; and, 3rd, domicile by operation of law, as that of a wife, arising from marriage.

Personal property must be distributed according to the law of the country in which the deceased was domiciled at the time of death. So also, according to our present law, a will is treated as valid or not, as it is or is not executed in conformity with the law of the country in which the testator died domiciled. The validity of a marriage will depend on the law of the country in which it takes place, provided the parties thereto are *bonâ fide* domiciled in that country, but the resort to a foreign country for the purpose of benefiting by the laxity of foreign law in respect of marriage will not avail, unless there be a *bonâ fide* domicile in that foreign country. In England every person, whether native or foreigner, who is for the time being within England, is amenable to the jurisdiction of its civil courts, and may sue or be sued in them. In Scotland, when the subject of dispute is within the jurisdiction of the courts, an action regarding it may proceed there, and any one who has property within their jurisdiction may be made amenable to the extent of that property. But actions of personal status, as for divorce, establishing a marriage, &c., can only proceed when the parties have established a domicile there by residence for forty days.

(On this subject, see Phillimore on *Domicile*, and Story's *Commentaries on the Conflict of Laws*, c. iii.)

DOMINANT, in music, the fifth of the key. Thus, if the key be C, the dominant is G.

DOMINICAL LETTER (*dies domi'nica*, Sunday). To every day in the year is attached one of the first seven letters, A, B, C, D, E, F, G; namely, A to the first of January, B to the second, &c.; A again to the eighth of January, and so on. The consequence is, that all days which have the same letter fall on the same day of the week. The *dominical letter* for any year is the letter on which all the Sundays fall. Thus, the first of January, 1854, being Sunday, the dominical letter for 1854 is A. In a common year, the first and last days have the same letters, whence the dominical letter of the succeeding year is one earlier in the list: that is, the dominical letter for 1855 is G. But in leap-year, it is to be remembered that the 29th of February has no letter attached to it: whence every leap-year has two dominical letters, the first for January and February, the second for all the rest of the year, the second being one earlier than the first. The following will now be easily understood; each year is followed by its dominical letter; 1853, B; 1854, A; 1855, G; 1856, F, E; 1857, D; 1858, C; 1859, B; 1860, A, G.

As it is convenient in historical reading to be able to find the day of the week on which a given day in a distant year fell, we subjoin the following tables. The middle column of figures contains the tens and units of the year in question, while the figures at the head contain the hundreds and tens of hundreds. Thus for the years 536 and 1772, look for 36 and 72 in the middle column, and for 5 and 17 at the head. On the left of the middle column is all that relates to the *old style;* on the right all that relates to the *new style.* The large letters on the left refer to years after Christ, the small letters to years before Christ.

OLD STYLE. The large letters refer to years *after* the Christian Era, and the small letters to years *before* it.											NEW STYLE.

Example 1. What was the dominical letter of the year 763, *before Christ*, old style? Look on the left, opposite to 63, in the column which has 7 among the headings, and the *small letter* there found is *c.* Hence E was the dominical letter of 763 B.C., or the fifth of January was a Sunday.

Example 2. What is the dominical letter of 1819, *after Christ*, old style? Look on the left, opposite to 19, in the column which has 18 among its headings, and the large letter there found is E. Hence E is the dominical letter of 1819 (old style), or the fifth of January was a Sunday.

Example 3. What will be the dominical letters of the year 1896, new style? Look on the right, opposite to 96, in the column which has 18 among the headings, and E D is found. Hence in this leap-year E is the dominical letter for the opening of the year, or the fifth of January will be a Sunday, and after February the dominical letter will be D.

Having found the dominical letter for a given year, the following table will assist in finding the day of the week upon which a given day of the month falls. It is the list of days which have A for their letter.

January	1	8	15	22	29
February	5	12	19	26	..
March	5	12	19	26	..
April	2	9	16	23	30
May	7	14	21	28	..
June	4	11	18	25	..
July	2	9	16	23	30
August	6	13	20	27	..
September	3	10	17	24	31
October	1	8	15	22	29
November	5	12	19	26	..
December	3	10	17	24	31

Thus the dominical letter being E, we ask on what day the 20th of July falls. The E being Sunday, the A is Wednesday, and July 16 is Wednesday, whence July 20 is Sunday.

DOMINICANS. [Black Friars.]

DONATIO MORTIS CAUSA, a gift made in prospect of death. The doctrine is derived from the civil law, and a donation of this kind is defined in the 'Institutes' (lib. ii. tit. 7) as "a gift which is made under an apprehension of death, as when a thing is given upon condition that, if the donor die, the donee shall have it, or that the thing given shall be returned if the donor shall survive the danger which he apprehends, or shall repent that he has made the gift; or if the donee shall die before the donor." In the English law it is necessary to the validity of this gift that it be made by the donor with relation to his dying by the illness which affects him at the time of the gift, but it takes effect only in case he die of that illness. There must be a delivery of the thing itself to the donee; but in cases where actual transfer is impossible, as, for instance, goods of bulk deposited in a warehouse, the delivery of the key of the warehouse is effectual. A donatio mortis causâ partakes of the nature of a legacy so far as to be liable to the debts of the donor, and, by 36 Geo. III., c. 52, s. 7, to the legacy duty; but as it takes effect from the delivery, and not by a testamentary act, it is not within the jurisdiction of the ecclesiastical court, and neither probate nor administration is necessary, nor the assent of the executors, as in the case of a legacy.

On the Roman donatio mortis causâ the reader may consult 'Heineccius;' and the 'Digest,' lib. xxxix., tit. 6. As to the Scotch law, see 'Ersk. Instit.' lib. iii., tit. 3, s. 91.

DONATISTS. [Donatus, in Biog. Div.]

DONATIVE. [Benefice.]

DOOMS, FALSING OF, a term of the old Scots law, somewhat similar in import with appeal of false doom, or writ of false judgment in the law of England. A doom or judgment thus falsed or charged with injustice, was of old taken from the bailies of burghs to the court of Four-boroughs, or from the court baron or freeholder's court to the court of the sheriff, and from either to the justice ayre, and thence to the parliament. The proceeding has long been obsolete.

DOOR. The movable panel by means of which the space of a passage or opening in a wall is closed, is technically known as a door (from the Teutonic root *Thor*, or *deur*); and it may be executed of various materials according to the purposes the opening itself is intended to serve. There are bronze, stone, iron, and wooden doors: and an infinite number of varieties of each of those descriptions of material.

Wooden doors are those which are the most commonly used, and therefore they are the ones it would be desirable to notice before the others. They are either framed, or panelled; or they consist of close, or open, boarding, kept together by ledges, or by bracing. Panelled doors are said to be square framed, moulded, bolection moulded, bead flush, or bead butt, according as they may be made to assume either of these forms of framing [Joinery]: and they may present those characters on one or two sides, as the case may be. The simpler boarded doors may either be composed of close, clamped boarding; or they may be ledged doors, with merely the horizontal pieces required to keep the boards in their places, and to receive the hinges; or they may be ledged and braced, with the horizontal ledges, which are kept from warping, or deforming, by means of angular braces. Ledged doors are usually cheaper than framed ones, and therefore are used for commoner descriptions of buildings; whilst the panelled doors, from the fact of their being susceptible of receiving ornamental decoration, are exclusively used in buildings of importance. In many cases the more costly kinds of wood are used for doors, either solidly, or as veneers; and of late years much attention has been paid to their decoration, by means of the application of glass, porcelain, and other costly furniture. [Ironmongery.]

Iron doors are frequently used for the purpose of intercepting the communication of fire, or for closing the entrances of strong rooms or safes; and in such cases they are made to assume the general character of the other doors in the building wherein they are placed. Whatever appearance may be thus given to them, it is essential that they should have a double case; and although cast-iron doors may in some cases present a satisfactory degree of strength and durability, yet, as a general rule, it is preferable to make the doors of strong rooms entirely of wrought iron, especially where there may be any possible danger from fire.

Bronze doors are only used in the decoration of large public or ecclesiastical buildings; and when so employed they are made to receive the highest description of artistic decoration. There are few specimens of this class of work in our own country; but abroad they have been frequently executed, as in the Pantheon of Rome, the celebrated gates of the Baptistery of the Cathedral of Florence, by Ghiberti, or more recently in the doors of the Madelaine, and of the church of St. Vincent de Paul, at Paris.

Stone or marble doors have occasionally been executed in public buildings, and especially in cemeteries; but their great weight must always constitute a serious objection to them. Some of the marble gates and doors of the Belgian churches may especially be referred to as illustrating this species of decoration; and the very remarkable real and false stone doors of the tombs at Aizani (figured in Téxier's 'Asie Mineure'), may be cited as illustrations of the ancient practice in such works.

In describing the various kinds of doors, of whatsoever material they may be composed, it is essential to observe that the following names are applied. Doors may be *real* or *false*; they may be *single*, or *double*; *entire*, or cut into two, or more, *hatches*; and again *single*, or *folding*; or if divided from top to bottom they may be in one or more *leaves*; whilst a small door formed in part of a larger one is called a *wicket*. A *trap* door is one which closes a horizontal opening; a *jib* door is one which closes a vertical opening so as to conceal the latter; a *swing* door is one which, not being stopped by the rebate of the door-frame, is able to pass over more than the quadrant of revolution of ordinary doors; and *rolling*, or *sliding* doors are those which move laterally upon rollers or runners, so as to avoid their development into the rooms they are intended to close.

On many occasions, it may be added, wooden doors were very elaborately carved: as in the case of the doors of St. Maclou, of Rouen, carved by Jean Goujon.

DOORWAY. An opening in the walls or partitions of a building, by means of which access is obtained from one part thereof to another, and which is closed by a door; and it is on this account that a *door* differs from a *window*, which is an opening made for the purpose of receiving light only. A *doorway* differs again from a *gateway* in this respect, namely, that the former is made in a wall, which is under any circumstances carried above it; whilst a gateway is formed in an inclosure, or railing, or fence, which does not exceed the height of the movable panel by which the gateway itself is closed. Habitually the term doorway is specially applied to the openings in houses, or public buildings; that of gateways to those of fence railings.

In doorways the sides, or the *jambs*, and the head or *lintel*, are frequently made the subjects of the most elaborate ornamental decoration, and much of the architectural expression of a building depends on the manner in which this detail is treated. In Greek, Hindoo, Egyptian, and Assyrian architecture, the doorways are almost invariably executed with straight lintels; and from the remains of the tombs of Lycia it would appear that this mode of treating the door openings was founded upon the original practice of the builders in wood, for the trabeated character of those openings is manifestly copied from the ancient log cabins, which must have surrounded the artists who designed those remarkable sepulchres. In the Roman, and the Byzantine, Saracenic, and Gothic styles, however, doorways were frequently, and latterly exclusively, made with arched openings, modified in each case by the spirit of the rest of the design, and by the purpose for which the building was intended, or by the description of door to be used. Thus, a doorway in the inclosure wall of a town would be provided with a portcullis as an additional defence, and therefore would have deep reveals; the doorways of ordinary buildings would simply be modified according to whether the doors were in one or two leaves, or whether they opened inwardly, outwardly, or were hung on rollers.

Constructively the most important considerations with respect to doorways are, firstly, those relating to the power of the jambs, on which the doors are hung, to resist the action of the revolving weight, and the jar arising from the abrupt closing of the door; and, secondly, those relating to the power of the lintel to resist the superincumbent pressure, and to maintain the jambs in their vertical positions. It is in order to secure the latter condition, also, that door *cills*, or transverse stiffening pieces, are introduced at the feet of the jambs. Very frequently the strain is removed from the lintel by means of what is called a discharging arch; and in many cases this contrivance is made to add considerably to the picturesque effect of a doorway, by the application of polychromic materials.

The sizes of doorways are usually made in England from 7 feet 6 inches high by 3 feet 6 inches wide, to 8 feet 6 inches by 4 feet 6 inches for external doors; 7 feet by 3 feet is the usual size for internal doors, and 6 feet 9 inches by 2 feet 10 inches is the minimum size adopted in such cases. The minimum size of folding doors is from 8 feet 6 inches to 9 feet high, by from 5 feet 6 inches to 6 feet wide; these dimensions, however, may be increased to almost any extent to suit the size of the rooms.

The best illustrations of doorways are to be found in the works of Professor Donaldson, 'Doorways from Ancient and Modern Buildings;' Téxier's 'Arménie,' and his 'Asie Mineure.'

DORADO (constellation), the sword-fish, a constellation of Bayer, situated in the southern hemisphere, and cut nearly in half by a line joining α Argûs and α Eridani. The principal stars are as follows:

Character.	No. in Catalogue of Lacaille.	No. in Catalogue of British Association.	Magnitude.
γ	327	1331	4
α	356	1438	3
β	436	1791	4

DORIC ORDER. [Greek Architecture.]

DORSTENIA, a genus of plants of the family of the *Urticaceæ*. The roots of several species of this genus, natives of Mexico, New Spain, and some West Indian islands, are all confounded under the appellation of Contrayerva root, but as they all possess nearly the same chemical composition and properties, it is of little importance which particular species yields what is used. Indeed, by the time the root reaches Europe, whatever virtues it originally possessed are lost, so that it has scarcely any sensible qualities, and very little effect on the system. It consists of volatile oil, extractive, and starch. The first of these gives it some power over the nervous system, should it not have been dissipated by time. Hence it is recommended in the low stages of fever, especially of children; but serpentaria root may at all times be advantageously substituted for it. Contrayerva signifies antidote, and it was at one time supposed to be an antidote to all poisons, whether animal, vegetable, or mineral, except mercury.

Contrayerva is now properly omitted from the 'London Pharmacopœia.' It has no place in the pharmacopœia of the United States, though it may be obtained there much fresher. The root of *Dorstenia Braziliensis* is certainly powerful when fresh, and often acts as an emetic—a property rendering it useful in fevers.

DORT, SYNOD OF, an assembly of Protestant divines convoked at Dort (Dordrecht), in the year 1618, by the States General, under the influence of Prince Maurice of Nassau, by which the tenets of the Arminians, in five points, relating to predestination and grace, were condemned by the followers of Calvinism.

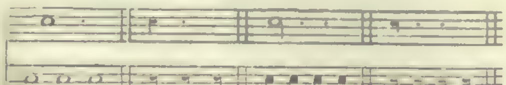
At this synod ecclesiastical deputies were present from most of the States of the United Provinces, and from the churches of England, Hesse, Bremen, Switzerland, and the Palatinate. Those from England were Dr. George Carleton, bishop of Landaff; Dr. John Davenant, regius professor of divinity at Cambridge, and master of Queen's College; Dr. Samuel Ward, master of Sidney College; and Dr. Joseph Hall, then dean of Worcester, but afterwards bishop of Norwich. Dr. Hall's health, after two months, requiring his return, he was replaced by Dr. Thomas Goad. To these was afterwards added Walter Balcanqual, a Scots divine, deputed by King James on behalf of the churches of that nation. The synod was opened on November 13, 1618; it consisted of thirty-eight Dutch and Walloon divines, five professors of universities, and twenty-one lay-elders; the foreign divines amounted to twenty-eight. Those from England had the precedence, after the deputies of the States.

Of the disputes which had prevailed in Holland for some years, between the Calvinists and Arminians, previous to the convocation of this synod, we have already spoken in the Biog. Div., in the notices of Arminius and of Barneveldt, the grand pensionary, whose fate was sealed when it had been sanctioned by the decision of this assembly.

In the sixth session, which was held on the 19th of November, 1618, the synod of Dort proposed obtaining a translation of the Bible from the original texts into Dutch, which was judged to be a necessary work. In the seventh, and some of the succeeding sessions, the translation was finally agreed to, and rules laid down for the direction of the translators. In the thirteenth session, on the 26th of November, the translators were appointed, when the following were chosen by a majority of votes: John Bogerman, the president of the synod; William Baudart and Gerson Bucer, for the Old Testament; Jacobus Roland, Herman Faukelius, and Peter Cornelius, for the New Testament and Apocrypha. The synod then chose sixteen supervisors of the translation; and also resolved, that in case any of the translators should die or be disabled by sickness, the president, with the two assessors, and the scribes of the synod, should be empowered to appoint successors.

After a delay of nearly ten years, the translators of the Old Testament assembled at Leyden, in 1628, and the next year, 1629, the translators of the New Testament; but as Herman Faukelius, pastor of the church of Middleburg, and Peter Cornelius, pastor of the church of Enchusan, had died previous to their meeting together, Anthony Walæus and Festus Hommius were chosen in their stead. When the translation of the Old Testament had advanced as far as the first chapter of Ezekiel, Gerson Bucer died, and was succeeded in his office by Anthony Thysius; Jacobus Roland also died when the translation of the New Testament had advanced to the Acts of the Apostles. The translation of the entire Bible was completed in 1632. The supervisors of the Old Testament met at Leyden, with the translators, in 1633; and those of the New Testament in 1634: and the revision was completed in October, 1635. The printing of the Bible was finished in 1637, when it appeared in folio from the presses of Leyden and the Hague, and in octavo from the press of Amsterdam. This is what is called 'The Dort Bible.' Editions of it were soon rapidly multiplied and extensively circulated.

DOT, in Music, a point, or speck, placed after a note or rest, in order to make such note or rest half as long again. Thus a semibreve with a dot is equal to three minims: a crotchet rest with a dot is equal to three quaver rests. In modern music a double dot is often used, in which case the second is equal to half of the first. Thus a double dotted minim is equal to three crotchets and a quaver; a double-dotted quaver rest is equal to three semiquaver rests and one demisemiquaver rest. Examples:—



DOUAY BIBLE. [Bible.]

DOUBLE-BASE, the largest musical instrument of the viol kind. [Viol.] In England, Italy, and France, the double-base has three strings, which are tuned in fourths:

(*An octave lower.*)

In Germany a fourth string is used, tuned a fourth below the deepest of the above.

The double-base, in full orchestral pieces, takes the notes written for the violoncello, when not otherwise directed, and if these are not too rapid, but always gives them an octave lower. It may be considered as the foundation of the band, for a want of firmness in this instrument is more fatal in its consequences than unsteadiness in any other.

In our concerts the Italian name of this instrument, *Contra-basso* (or, more strictly, *Contrab-basso*), is as frequently employed as its English appellation.

DOUBLE STARS. [Stars, Double.]

DOUBLETS. In optical instruments where high powers are required there is much practical inconvenience in forming single lenses of short focal length. The difficulty has been obviated by the use of magnifiers formed of two or more lenses combined. The most efficient are two or three plano-convex lenses, with their convex sides towards the eye, and are hence called *doublets* or *triplets*.

DOUBLOON. [Money.]

DOUCHE. [Bathing.]

DOVETAIL, a term in construction. A dovetail is the end of a piece of wood or metal fashioned into the fan-like form of a dove's tail, and let into a corresponding hollow of another piece of wood, stone, or metal. Dovetails are either exposed or concealed; "concealed dovetailing is of two kinds, lapped and mitred." Dovetailed metal cramps are much used in masonry.

DOWER (Law) is that part of the husband's lands, tenements, or hereditaments which come to the wife upon his death, not by force of any contract expressed or implied between the parties, but by operation of law, to be completed by an actual assignment of particular portions of the property.

Prior to the reign of Charles II., five, and until the passing of the Act 3 & 4 Will. IV., c. 105, four kinds of dower were known to the English law.

1. Dower at the common law.
2. Dower by custom.
3. Dower ad ostium ecclesiæ.
4. Dower ex assensu patris.
5. Dower de la plus beale.

This last was merely a consequence of tenure by knight's service, and was abolished by stat. 12 Charles II. c. 24; and the 3rd and 4th, having long become obsolete, were finally abolished by the above-mentioned statute.

By the old law, dower attached upon the lands of which the husband was seised at any time during the marriage, and which a child of the husband and wife might by possibility inherit; and they remained liable to dower in the hands of a purchaser, though various ingenious modes of conveyance were contrived, which in some cases prevented the attaching of dower; but this liability was productive of great inconvenience, and frequently of injustice. The law too was inconsistent, for the wife was not dowable out of her husband's equitable estates, although the husband had his courtesy in those to which the wife was equitably entitled. [Courtesy.] To remedy these inconveniences the statute above mentioned was passed, and its objects may be stated to be: 1, to make equitable estates in possession liable to dower; 2, to take away the right to dower out of lands disposed of by the husband absolutely in his life or by will; 3, to enable the husband, by a simple declaration in a deed or will, to bar the right to dower. This could always have been done by levying a fine, an expensive and inconvenient remedy: while the increase of personal property, and the almost universal custom of securing a provision by settlement, afforded effectual and convenient means of providing for a wife.

Dower at the common law is the only species of dower which affects lands in England generally; dower by custom is only of local application, as dower by the custom of gavelkind and Borough English; and freebench applies exclusively to copyhold lands.

In order to describe dower at the common law clearly, it will be advisable to follow the distribution of the subject made by Blackstone.

1. Who may be endowed.
2. Of what a wife may be endowed.
3. How she shall be endowed.
4. How dower may be barred or prevented.

1. *Who may be endowed.*—Every woman who has attained the age of nine years is entitled to dower by common law, except aliens, and formerly Jewesses, so long as they continued in their religion. From the disability arising from alienage, a queen, and also an alien licensed by the sovereign, are exempt.

2. *Of what a wife may be endowed.*—She is now by law entitled to be endowed, that is, to have an estate for life in the third part of the lands and tenements of which the husband was solely seised either in deed or in law, or in which he had a right of entry, at any time during the coverture, of a legal or equitable estate of inheritance in possession, to which the issue of the husband and wife (if any) might by possibility inherit.

3. *How she shall be endowed.*—By Magna Charta it is provided, that the widow shall not pay a fine to the lord for her dower, and that she

shall remain in the chief house of her husband for forty days after his death, during which time her dower shall be assigned. The particular lands and hereditaments to be held in dower must be assigned by the heir of the husband, or his guardian, by metes and bounds if divisible, otherwise specially, as of the third presentation to a benefice, &c. If the heir or his guardian do not assign, or assign unfairly, the widow has her remedy at law, and the sheriff is appointed to assign her dower; or by bill in equity, which has long been the usual remedy.

4. *How dower may be barred or prevented.*—A woman is barred of her dower by the attainder of her husband for treason, by her own attainder for treason, or felony, by divorce *à vinculo matrimonii*, by elopement from her husband and living with her adulterer, by detaining the title-deeds from the heir at law, until she restores them, by alienation of the lands assigned her for a greater estate than she has in them; and she might also be barred of her dower by levying a fine, or suffering a recovery during her marriage, while those assurances existed. But the most usual means of barring dower are by jointures, made under the provisions of the 27 Hen. VIII., c. 10; and by the act of the husband. Before the stat. of Will. IV., a fine or recovery by the husband and wife was the only mode by which a right to dower which had *already attached* could be barred, though, by means of a simple form of conveyance, a husband might prevent the right to dower from arising at all upon lands purchased by him. By the above-mentioned statute, it is provided that no woman shall be entitled to dower out of any lands absolutely disposed of by her husband either in his life or by will, and that his debts and engagements shall be valid and effectual as against the right of the widow to dower. And further, that any declaration by the husband, either by deed or will, that the dower of his wife shall be subjected to any restrictions, or that she shall not have any dower, shall be effectual. It is also provided that a simple devise of real estate to the wife by the husband shall, unless a contrary intention be expressed, operate in bar of her dower. As to the law of dower in the United States of America, see vol. iv. Kent's 'Commentaries.'

DOWNS. [DUNES.]

DOXOLOGY, a form of giving glory to God, from the Latin *doxologia*, and that from the Greek *doxa* (δόξα), glory, and *logos* (λόγος), a word or saying. The doxology in the concluding paragraph of the Lord's Prayer, "Thine is the kingdom, and the power, and the glory," is left out of many of the ancient copies of St. Matthew's Gospel, though it appears in others; St. Luke omits it entirely. The authenticity of this form of praise, as a paragraph of the prayer, has been a difficult subject of dispute. It does not appear in the Vulgate, but it seems to be established by the Greek MSS. and the Eastern versions. Doxology is also used for the verse used in the Common Prayer, from Luke ii. 14, "Glory to God in the highest, and on earth peace, good will to all men;" and for the short hymn, *Gloria Patri*, which we use in our church service at the end of every psalm, and of every hymn except *Te Deum*, which is a doxology of itself. Durand and other writers consider this exception to have been introduced into the Romish church by St. Jerome. The first express mention of it is in the second council of Vaison, A.D. 529. Amongst the early Christians it was always considered as a solemn profession of their belief in the Trinity.

DRACHM. [DRAM.]

DRACHMA, from the Greek *drachme* (δράχμη), a silver coin, the unit of the Greek coinage. The value of the drachma varied in the different provinces of Greece: though it was the chief coin in use among the Greeks. A talent contained 10,000 drachmæ reckoned by weight, but a talent of gold was worth 120,000 silver drachmæ. The didrachm or two drachms, the tridrachm or three drachms, and the tetradrachm or four drachms, were its multiples. The last was the largest form of Greek silver. The average weight of five drachmæ in the British Museum is 60·92 grains; and the average weight of three tetradrachmæ in the British Museum is 260·56 grains. The Attic drachma has been supposed to have been the same among the Greeks with the denarius among the Romans: others have disputed this; but both may be reconciled by the consideration that the number of drachmæ, as well as of denarii, which went to the ounce, might have been subject to occasional variations.

Drachma.

British Museum. Actual size. Silver. Weight, $61\frac{7}{10}$ grains.

DRACINA, the name given by Melandri to the colouring-matter of dragon's blood, and which he supposed to be a vegetable alkaloid; but Berzelius and Herberger are of opinion that it does not possess alkaline properties: the last-mentioned chemist, indeed, calls this colouring-matter *draconin*, and he considers it to possess rather sub-acid properties than such as denote alkalinity.

DRACO (the dragon), one of the old constellations, referred by Hyginus to the fable of the Hesperides. It is constantly stated by the older writers as being placed between Ursa Major and Ursa Minor, which hardly suits the present position of the constellation, since its principal stars are all contained between Ursa Minor, Cepheus, Cygnus, and Hercules. The two stars in the head (β and γ, the latter celebrated as passing very near the zenith of the south of England, and as being the one used in the discovery of aberration [BRADLEY, BIOG. DIV.]) are nearly in the line joining α Cygni (Deneb) and Arcturus; while seven or eight smaller stars wind round Ursa Minor in such a manner as to render the name of the constellation not unappropriate. The extreme star (λ) is very nearly between the pole star and its pointers. [URSA MAJOR.] The principal stars are as follows:—

Character.	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
λ	1	3914	3·5
κ	5	4239	3·5
α	11	4696	3·5
ι	12	5097	3
θ	13	5348	3
η	14	5512	3
A	15	5545	4
μ′	21	5785	4
ζ	22	5823	3
β	23	5937	2·5
ω	28	6006	4
ξ	32	6079	3·5
γ	33	6091	2
χ	44	6302	4·
δ	57	6612	3
π	58	6662	4
τ	60	6650	4·5
σ	61	6735	4

DRACONIC ACID. [ANISIC ACID.]

DRACONIN, the *dracina* above mentioned, may be obtained, according to Melandri, by macerating dragon's blood in water acidulated with sulphuric acid: this becomes of a yellow colour, but does not act upon the draconin, which is of a fine red colour, and very fusible; it may be worked between the fingers, and drawn into threads. It melts at about 130°; on solidifying it becomes of a crimson colour, and when triturated gives a cinnabar red colour. It dissolves readily in alcohol, and the solution, which is of a fine red, becomes yellow on the addition of an acid; but on the addition of an alkali the red colour is restored. It does not appear to have been analysed.

DRACONYL. [STYROL.]

DRACYL. [TOLUINE.]

DRAGOMANS, or DROGOMANS (from the Turkish *Trukéman*); the term by which the interpreters attached to the European consulates and embassies in the Levant are known. At Constantinople they are the chief, and in most cases the sole medium of communication between Christian ambassadors, who are ignorant of the Turkish language, and the Ottoman Porte; several are attached to every embassy, and the consuls in the Turkish dominions generally have one. They are men born in the country, and are chiefly descended from old Genoese or Venetian settlers. Their local interests and sympathies have often interfered with their duties; and though there have been honourable exceptions, they are not distinguished as a body for honour and integrity. Austria and France, however, have the privilege of appointing one of their own subjects to the office. The French, as early as the time of Louis XIV., instituted a small body of young men, technically called *Jeunes de langue*, who were sent to the country to learn the language and acquaint themselves with its laws and customs; and Austria maintains an Oriental academy at Constantinople, to enable young men to qualify themselves. The dragomans and their families enjoy the protection of the nations whom they serve, and are exempted from Turkish law.

DRAGON'S BLOOD, the produce of various species of Calamus, is sent to Europe in several forms. 1. Dragon's blood in tears (sanguis D. in lachrymis); 2. Dragon's blood in grains (S. D. in granis); 3. Dragon's blood in reeds (S. D. in baculis), in rods about 1 to 1½ feet long, about the thickness of the finger, covered with the fronds of the palm, wrapped round it with split branches. This is the best kind now met with in European commerce.

Many other kinds of dragon's blood are procured from different trees in various parts of the world, of which two only are worthy of notice: 1. Dragon's blood in masses, obtained both in the East Indies and Madeira by wounding the stem of the *Dracæna Draco* (Linn.), occurs in large shapeless masses of a violet colour. 2. S. D. de Carthagena, American or West Indian dragon's blood, obtained from the *Pterocarpus Draco* (Linn.). It occurs in pieces about 12 or 14 inches long, with a sharp angle on one side, partly wrapped up in the tendrils of a cissus and in leaves. Dragon's blood is a peculiar resinous colouring principle (*Draconia*), mixed with benzoic acid and other matters. It is insoluble in water, but easily soluble in alcohol, especially when boiling; it is also soluble in watery solutions of the caustic alkalies, and forms with them a violet coloured solution; it is less soluble in ethers and oils, but soluble in acetic acid. Sulphuric acid chars it. Analysed by Herberger, 100 parts yielded—

Fatty matter	2·00
Oxalate of lime	1·60
Phosphate of lime	3·70
Benzoic acid	3·00
Draconia	70·70

According to Herberger, draconin is not an alkaloid, as Melandri thought, but a sub-acid. ('Journ. de Pharm.,' xvii. p. 225.)

Dragon's blood possesses no astringent properties, as was once supposed to be the case, owing to kino being confounded with it. It is now seldom used internally, but it is added to tooth-powders. It is however employed as a colouring matter and an ingredient in varnishes.

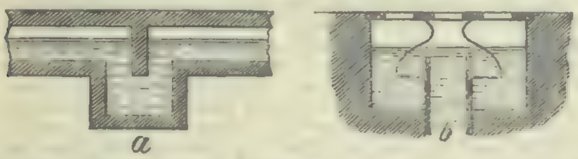
A spurious dragon's blood is often made with colophony, olibanum, turpentine, &c., coloured red with powdered Saunder's-wood. Gum Senegal is also dyed red with tincture of Saunder's-wood and passed for dragon's blood. The spurious is wrapped in the leaves of the Zea Mais, or Indian corn.

Dragon's blood was known to the Greeks, and by them called *κινναβαρις, cinnabar*, a name which they also gave, as we now do, to a mineral, the red bisulphuret of mercury or *minium*.

DRAGOON. [CAVALRY.]

DRAIN. An artificial channel formed in the ground for the purpose of removing the surplus waters, whether they be supplied from the atmosphere or from land springs. These drains may be formed either of loose stones, of pipes of ordinary brick earth or of stoneware, or of masonry or brickwork, according to the nature and quantity of the water to be removed, or to local conditions of economy. Drains are classified under the names of sub-drains, main-drains, and outfall-drains, according to the functions they may discharge in a system.

DRAIN-TRAP. A pit formed at the entrance to a drain, for the purpose of preventing the escape of the mephitic gases which are frequently given off from the waters collected by a system of drainage; and also of preventing, as much as possible, the introduction of sand, drift, or other encumbering materials, into the subterranean channels. The pit contains, usually, a species of hydraulic seal, which constitutes, in fact, the trap, formed by means of a tongue descending below the surface of the water, as in sketch *a*, when the trap is placed in the course of the drain; or by a solid bell-covering, the lip of which dips into the water in the ordinary bell traps, such as are used in London houses for sinks, drains, rain-water-pipes, &c. A siphon bend in the course of a drain-pipe will constitute an efficient drain-trap, so far as the prevention of smell only is concerned; but it is exposed to the serious objection of being likely to become choked, if the waters should transport much suspended matter.



DRAINAGE. The removal from the ground of any waters whose sojourn might be pernicious, from whatever source they may be supplied, and the provision of an adequate discharge for those waters, constitute the art of drainage, which has at all times engaged the most serious attention of the hydraulic engineer. The Egyptians and the Assyrians at a very early period executed some curious drainage works, the remains of which still survive; and the Etruscan predecessors of the Roman civilisation practised the art with great success, as certainly was proved by the extraordinary operations effected under the reign of Tarquinius Priscus for the drainage of the low lands at the feet of the seven hills. The Romans themselves devoted a great deal of attention to this subject; and there are in the treatises of Columella, Varro, Cato, on agriculture, and in the books of Vitruvius and Pliny, many remarkable passages illustrating the practice of the Romans in this branch of applied sciences. In the middle ages the art of drainage seems to have been lost sight of; and it was not until about the end of the 16th century that any great works of this description were undertaken. At that period, the Dutch engineers commenced the works for draining the lakes of the province of North Holland, which now constitute the fertile polders of the Purmer, Beemster, Woermer, &c.; and subsequently the great operation of draining the Bedford Level was commenced under the guidance of Sir Cornelius Vermuyden. All these works however were superficial, so to speak, and they were only executed in low-lying, swampy districts; but about the end of the last century Elkington turned his attention to the removal of the injurious waters of upland districts, and the art of drainage rapidly assumed, in consequence of his success, the peculiar character which it now bears. Messrs. Smith of Deanstone, Parkes, and Bailey Denton, have perhaps been the persons who have contributed the most to its advancement.

From this brief sketch of the history of drainage, it will be seen that it may be divided into two great branches, namely, the drainage by means of open cuts, or the drainage by means of subterranean channels; and again, of late years, a distinction has been made between rural and urban drainage, because the latter has been made to comprehend the removal of household refuse in the form usually known as sewerage.

Drainage by open cuts of course can only be applicable when the waters to be removed do not attain a level superior to that of the ground, and when there is an efficient outfall, either natural or artificial; and its success depends upon the maintenance of a regular permanent discharge of the waters supplied by the collecting drains. The surface of the water in these collecting drains must always be kept at such a distance from the surface as to prevent any injurious action upon the vegetation of the land, for it is to be observed that drainage by open cuts is almost exclusively reserved for agricultural districts. In the outfall drains, the water must not be allowed to stagnate, and the cuts must be formed of such dimensions, and in such directions, as to ensure the discharge in the smallest possible time. The rules for calculating the areas and the inclinations of these drains will be found under HYDRAULICS.

In such cases as those of the polders of Holland, and of the fen districts of the east of England, where the natural surface of the land is beneath the mean water level of the surrounding country, it was found necessary to isolate the land about to be drained, and to create an artificial outfall into which the waters were raised, by artificial means, to a level which would allow of their subsequent discharge. The Dutch engineers call these out-falls when they surround a previously submerged district, "ring dykes;" and generally speaking, they raise the drainage waters into them by means of Archimedian screws, or of dash wheels, worked by windmills of a very rude and primitive construction. In the drainage of the Haarlem lake, however, steam power was resorted to, and the water from the submain drains is led, through large cuts, to the pumps of some immense Cornish engines of about 400-horse power each, to be raised by them into the ring dyke, whose dimensions are not less than 125 feet in width by 10 feet deep on the average. The outfall of the ring dyke of the Haarlem lake is into the Spaarn, a river falling ultimately into the Zuyder Zee; and, as the Spaarn is itself frequently closed by high tides or by storms, an elaborate system of stop gates, and some large steam-pumping engines, working a set of dash-wheels, is provided to ensure the discharge of the land waters during those periods. Very nearly the same principles have been adopted in designing the works lately executed in the fen districts of Cambridgeshire and Lincolnshire; but in these countries it often happens that the formation of a large intercepting drain (for the purpose of carrying off at once the upland waters, without their being allowed to pass into the drainage cuts of the lower level), will considerably diminish the duty required of the outfall drain. Local conditions must always affect these matters of detail; but the principle—the removal of the largest possible quantity of water by gravitation, instead of by artificial means—is of universal application.

The drainage of bogs, or swamps, in mountainous districts, may very often give rise to the application of other laws; as for instance, when the water, which maintains the permanent state of humidity it is desired to remedy, is supplied by springs rising under considerable pressure; or when the swampiness of the locality arises from the mere accumulation of water at the wet seasons of the year. The Bog of Allen was an instance of the former condition, and in that case the water was relieved by forming a series of artificial channels, or vertical pipes, through which it rose, and poured into a new outfall drain. The Chat Moss, however, was drained simply by means of open cuts, so traced as to carry off the surface waters as rapidly as they fell, and by a trifling improvement in the outfall. The latter operation is, moreover, the principal one required to obviate the supposed inconvenience from the occasional accumulation of rain waters; and it may be stated that there are many thousand acres of the best land in Europe, now unproductive, which might be easily brought into cultivation by the execution of some unimportant works to lower the level of the natural water courses of the districts in which these now valueless tracts are situated. In the north of Spain, in Switzerland, and in the island of Sardinia, there are numerous tracts which only require to be thus treated.

The works necessary for the drainage of a large morass, or fenny district, are usually of such a nature as to require the intervention of the legislature, or of the state; because they involve in many instances serious interference with private rights, and great changes in the hydrographical arrangements of the whole water shed with which they are connected. Perhaps Wells' history of the 'Bedford Level' may furnish some of the most valuable information upon this branch of the subject; or the series of Acts which govern the proceedings of the Commissioners of the Fen districts of Cambridgeshire, namely, 29 Geo. II., c. 22; 39 & 40 Geo. III., c. 26; 50 Geo. III., c. 194; or those lately passed for the regulation of the various Lands Drainage and Improvement Companies, may be referred to as illustrating the principles of legislation recently adopted in England in these matters. The reports by de Prony on the amelioration of the 'Pontine Marshes;' by Tartini, on the 'Maremme Toscane;' and by Fossombroni, on the 'Val di Chiana,' may be cited as illustrations of the scientific principles to be applied in designing the necessary works. Dugdale's 'History of Embankment and Draining,' may also be advantageously consulted, a may also the communications to parliament, by the Commissioners appointed to 'Report upon the nature and extent of the Irish bogs.'

A system of drainage exclusively by open cuts is, at the present day, so rare in our own country, and in fact in all countries, where there is the ordinary variety of hill and dale, that the meaning of the generic term, *drainage*, has almost been perverted to that of a subterranean drainage. There are, however, very essential differences between the conditions which are adapted to these respective modes of operation, and it is dangerous therefore to admit any confusion in the names by which they are characterised. One of the most important of these differences arises from the fact that in open drainage little reference need be made to the daily rain-fall, provided the outfall be established under such conditions as to prevent any serious accumulation of water, whilst the rain-fall of the particular district will regulate the dimensions to be given to a series of subterranean drains, in connection with the usual considerations with respect to the permeability of the strata. It usually happens also that little reference need be made to the permeability of the low lands, to which alone the open cut drainage can be economically applied; because the level of the water in the cuts is usually maintained at a permanent line, and it is only the excess of water which is removed. In fact, in the districts wherein drainage is effected by open cuts, the class of cultivation is usually such as to require the presence of a definite quantity of water in the subsoil, and, in the polders of Holland especially, very serious evil results from an abnormal lowering of the water line. In districts wherein subterranean drains are used, however, it is essential to remove as rapidly as possible any waters which might have a tendency to stagnate around the roots of the plants, or to prevent the surface of the ground from being cooled by the rising of springs. The practical details of the two systems of drainage are naturally much affected by these peculiar local conditions, and in the case of the subterranean drainage the physical outlines of the country will further affect the question, by reason of the greater or less facilities they offer for the throwing off, or retaining surface waters.

In properly drained land, situated at such levels as to allow the water collected in the outfall drains to flow freely, the surface of the ground is always dressed into such tables, or ridges, as to ensure the discharge of the water falling from the atmosphere which does not permeate the surface itself; and the drains have only to carry off the water which soaks through the ground. Evidently, under such circumstances, the drains must be placed at distances varying according to the degree of permeability of the ground, and also of the nature of the subsoil, though the latter condition would rather affect the depth of the drains than their lateral distances. Some discussion has taken place amongst the leading professors of the art with respect to these details; but they seem to have simply fallen into the error of all absolute theoreticians, for it must evidently be absurd to apply indiscriminately any system of either deep or shallow drains; and it must as evidently be the proper course to modify both the depth and the distance apart of the drains, according to local circumstances.

The only invariable condition affecting the depth of drains is, that they must be beyond the reach of any agricultural operations. In light lands the plough often does not descend more than 8 inches, and even in the most fertile districts of the North of Spain not more than 4 inches; whilst in heavy stiff clays, as in the island of Jersey, the depth of the plough is not less than from 18 to 20 inches. It is therefore customary to place the drains, even in what is called shallow drainage, at a minimum depth of from 20 to 24 inches, measuring from the top of the material constituting the channel to the surface of the ground. The maximum depth at which drains are laid does not exceed under any circumstances from 6 to 8 feet, and it is only occasionally that the depth is made more than 4 feet 6 inches from the surface. In shallow drainage the number of the drains is increased, and they are brought closely together; whilst in deeper drainage the distance is augmented. Smith of Deanstone, who was an advocate for shallow drains, usually made them from 6 to 8 yards apart, and about 3 feet deep. Parkes recommends, on the contrary, that the distances asunder should be made from 13 to 20 yards, and that the depth should be made from 4 feet 6 inches to 8 feet. The choice of the respective systems must, however, be regulated by the nature of the subsoil as much as by that of the soil itself, and very careful observations should be made before either of them is adopted.

The width of the trenches will be regulated by the depth of the drain rather than by any other condition, for it must be made wide enough to allow the workmen to perform easily any of the operations required for levelling the bottom of the excavation, or for placing the pipes or other materials. In practice it is found that, for a depth of 3 feet, it is sufficient to give a width of 1 foot at the surface and 3 feet at the bottom; for a depth of about 4 feet, these widths become respectively 1 foot 4 inches and 8 inches; whilst for a depth of 8 feet they become respectively 2 feet 6 inches and 1 foot 2 inches, even in hard resisting grounds, which are not likely to cave in, as the workmen say. The width of the bottom of the trench, it is to be observed, is regulated rather by the necessity for its being sufficiently wide to enable the workmen to lay the pipes than by any other condition; and it is also found, practically, that it is not possible to secure the regularity of the inclination of the bottom, unless the men can stand directly upon it. The success of a system of drainage depends greatly upon the last-named condition,—namely, the regularity of the inclination, as also upon its being made such as to ensure the constant flow of the water. Generally speaking, a fall of 1 in 200, in the minor drains, will suffice, especially when the drain-tiles have been well and carefully laid.

It is not desirable to make the sub-drains of any great length if their inclination should be considerable; because, under such circumstances, it is possible that the head of water in the pipes or channels might burst them, and there is always danger of an accumulation of silt. Generally speaking, the smaller drains do not exceed 100 yards in length before discharging into submains of larger dimensions; and the latter are limited to a length of about 300 yards before discharging into open ditches, or into the main outfall of the district. If it were possible, it would even be preferable to make the small pipes or channels themselves discharge into the open ditches, without using any sub-mains. An important remark to be made with regard to every description of subterranean channel is, that they must be carried as far as possible from trees or hedges; because the roots of the latter have a remarkable avidity for water, and they are sure to find their way into any channel in their immediate neighbourhood. The sub-mains should be laid a little below the ordinary line of the smaller channels, in order to communicate to the water a greater velocity when it approaches the point of junction; and the junctions should be made with a curve upon the plan, so as to avoid any direct interference with the lines of flow of the respective streams.

There are several modes employed for the purpose of filling in the trenches of drains, the choice of which must be regulated by local conditions of economy; though, as a general rule, it would unquestionably be better to resort to the use of pipes of stone or of earthenware. The cheapest, but also the least permanent, mode of forming the channel consists in cutting a species of shoulder near the bottom of the trench, upon which a thick sod of the grass from the surface is laid, with the grass downwards, and then filling in the remainder of the trench with light permeable earth. In countries where stones are easily obtained, it is customary to use them for the purpose of forming the channel; and this is effected by placing two slabs in an inclined position to one another, and covering them to a certain height with the smaller broken stones. Both the stone and the turf channels are, however, liable to become silted up, or even to be choked, by the precipitation of the salts which the waters may hold in solution; and it is on these accounts that agricultural engineers have, of late, given very decided preference to the use of tile or pipe drains. Formerly the tile and shoe drains were the most generally used; and, in filling them in, it was customary to lay flat tiles or shoes at the bottom of the trench, which shoes were made about 14 inches long and about 5 inches wide, and upon them to place the tiles, of the same length, and from 3 to 4 inches wide and 4 or 5 inches high. Of late years cylindrical tubes have been almost exclusively used, not only on account of the economy of their manufacture, but also of the greater ease and regularity with which they can be laid. These pipes are made of almost any diameter, from 1 foot to 1 inch, and of lengths varying from 14 inches in the smaller dimensions to 2 feet in the larger ones; the 2 inch pipes being generally used for the small drains, and the 4 or 6 inch pipes for sub-mains under normal conditions. When cylindrical pipes are used in peaty or very moveable soils, it is necessary to protect the abutting joints by means of collars; but in ordinary soils no such precautions are required to be observed. Drain-pipes of ordinary brick or tile earth are made in almost every county in England by a very simple species of machinery, and they are burnt in close kilns, the prices in the maker's yard being usually about as follows:—For pipes,

1 in. diam., the price is	4s.	6d.	per 1000,	and a cart with 4 horses can carry	8000
1½	"	6 0	"	"	7000
1¾	"	8 0	"	"	5000
2¼	"	10 0	"	"	3500
2½	"	12 0	"	"	3000

In the most economically constructed tile factories, indeed, it appears that the outlay upon plant is so small, that almost any large landed proprietor would have a direct interest in making tiles on his own account. The total expense of a Scragg's pipe-making machine, a pug-mill, drying-shed, and kiln to hold 40,000 tiles, would, according to Captain Johnston, not exceed 220*l*.

It may be here added, that the ordinary cost of pipe-drainage in clay land will vary, according to its more or less permeable nature, between 2*l*. 10*s*. to 5*l*. per acre: in rocky ground, of course the cost would be increased, but fortunately drainage is rarely required in such positions.

In town drainage it is important to observe that the system to be adopted will depend upon the consideration as to whether or not the surface or rain waters are to be carried off simultaneously with those furnished by the houses to which all modern improvements are applied. Drainage in itself is indeed distinct from sewerage; and the materials which are adapted for the one operation may be very inappropriate to the other—a fact which unfortunately has been overlooked by the official authorities who have lately assumed to teach local boards how they ought to execute sanitary works. For many reasons it will be preferable to defer the consideration of this subject to the article SEWERAGE; but it may be necessary here to observe that, especially in cases where a town may be situated upon the outcrop of a permeable stratum likely to feed any surface springs or watercourses, as Croydon or Ipswich, for instance, very serious evil would be produced by neglecting to provide as energetically for the removal of rain or of subterranean waters, as by neglecting to remove the house refuse. The impermeable stoneware drains, which it is now the fashion to recommend indiscriminately, are, in fact, very often a source of great mischief, unless they are accompanied by a series of permeable subsoil drains. The latter must be made of sufficient dimensions to carry off at once the maximum quantity of rain which may run off from the drainage area, and those dimensions must therefore be materially affected by the nature of the surface of the said area, or, in other words, by the consideration as to whether it be or be not built upon, or whether it be paved or merely ordinary ground; the relief of the surface will also materially influence the rapidity with which the rain-flow of a town will find its way into the drains. Generally speaking it is found, moreover, that the subsoil waters which find their way into town drains are exposed to such extraordinary chemical re-actions, that they are as little fitted to be poured into the superficial watercourses as even the waters of sewers.

DRAINING. As a certain quantity of moisture is essential to vegetation, so an excess of it is highly detrimental. In the removal of this excess consists the art of draining. The same, or nearly the same truth, may perhaps be better expressed thus: As water stagnant in the soil is prejudicial to the growth of all our cultivated plants, fertility is greatly promoted by the art of draining, which induces its circulation through the soil.

Water may render land unproductive by covering it entirely or partially, forming lakes or bogs; or there may be an excess of moisture diffused through the soil and stagnating in it, by which the fibres of the roots of all plants which are not aquatic are injured, if not destroyed.

From these different causes of infertility arise three different branches of the art of draining, which require to be separately noticed.

1. To drain land which is flooded or rendered marshy by water coming over it from a higher level, and having no adequate outlet below.
2. To drain land where springs rise to the surface, and where there are no natural channels for the water to run off.
3. To drain land which is wet from its impervious nature.

The first branch includes all those extensive operations where large tracts of land are reclaimed by means of embankments, canals, sluices, and mills to raise the water; or where deep cuts or tunnels are made through hills which formed a natural dam or barrier to the water. Such works are generally undertaken by associations under the sanction of the government, or by the government itself; few individuals being possessed of sufficient capital, or having the power to oblige all whose interests are affected by the draining of the land, to give their consent and afford assistance. In the British dominions there is no difficulty in obtaining the sanction of the legislature to any undertaking which appears likely to be of public benefit. In every session of parliament Acts are passed giving certain powers and privileges to companies or individuals, in order to enable them to put into execution extensive plans of draining. That extensive draining in the counties of Northampton, Huntingdon, Cambridge, Lincoln, Norfolk, and Suffolk, which is known by the name of the BEDFORD LEVEL [GEOG. DIV.], was confided to the management of a chartered corporation, with considerable powers, as early as the middle of the 17th century, and by this means an immense extent of land has been rendered highly productive, which before was nothing but one continued marsh or fen.

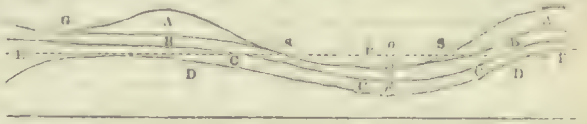
In the valleys of the Jura, in the canton of Neufchâtel in Switzerland, which are noted for their industry and prosperity, extensive lakes and marshes have been completely laid dry, by making a tunnel through the solid rock, and forming an outlet for the waters. All these operations require the science and experience of civil engineers, and cannot be undertaken without great means. The greater part of the lowlands in the Netherlands, and especially in Holland, have been reclaimed from the sea, or the rivers which flowed over them, by embanking and draining, and are only kept from floods by a constant attention to the works originally erected.

Where the land is below the level of the sea at high water, it requires a constant removal of the water which percolates through the banks or accumulates by rains; and this can only be effected by sluices and mills, as is the case in the fens in England. The water is collected in numerous ditches and canals, and led to the points where it can most conveniently be discharged over the banks. The mills commonly erected for this purpose are driven by steam-power, and are true water-wheels, lifting by their float-boards enormous quantities at every revolution from the lower to the higher level.

In hilly countries it sometimes happens that the waters which run down the slopes of the hills collect in the bottoms where there is no outlet, and where the soil is impervious. In that case it may sometimes be laid dry by cutting a sufficient channel all round, to intercept the waters as they flow down and to carry them over or through the lowest part of the surrounding barrier. We shall see that this principle may be applied with great advantage in many cases where the water could not be drained out of considerable hollows if it were allowed to run into them.

When there are different levels at which the water is pent up, the draining should always be begun at the highest; because it may happen that when this is laid dry, the lower may not have a great excess of water. At all events, if the water is to be raised by mechanical power, there is a saving in raising it from the highest level, instead of letting it run down to a lower from which it has to be raised so much higher.

The draining of land which is rendered wet by springs arising from under the soil is a branch of more general application. The principles on which the operations are carried on apply as well to a small field as to the greatest extent of land. The object is to find the readiest channels by which the superfluous water may be carried off; and for this purpose an accurate knowledge of the strata through which the springs rise is indispensable. It would be useless labour merely to let the water run into drains after it has sprung through the soil and appears at the surface, as ignorant men frequently attempt to do, and thus carry it off after it has already soaked the soil. But the origin of the springs must, if possible, be detected; and one single drain or ditch judiciously disposed may lay a great extent of land dry if it cuts off the springs before they run into the soil. Abundant springs which flow continually generally proceed from the outbreaking of some porous stratum in which the waters were confined, or through natural crevices in rocks or impervious earth. A knowledge of the geology of the country will greatly assist in tracing this, and the springs may be cut off with greater certainty. But it is not these main springs which give the greatest trouble to an experienced drainer; it is the various land springs which are sometimes branches of the former, and often original and independent springs arising from sudden variations in the nature of the soil and subsoil. The annexed diagram, representing a section of an uneven surface of land will explain the nature of the strata which produce springs.



Suppose A A to be a porous substance through which the water filtrates readily; and B B to be a stratum of loam or clay impervious to water. The water which comes through A A will run along the surface of B B towards S S, where it will spring to the surface and form a lake or bog between S and S. Suppose another gravelly or pervious stratum under the last, as C C C bending as here represented, and filled with water running into it from a higher level; it is evident that this stratum will be saturated with water up to the dotted line E F F, which is the level of the point in the lower rock, or impervious stratum D D, where the water can run over it. If the stratum B B has any crevices in it below the dotted line the water will rise through these to the surface and form springs rising from the bottom of the lake or bog; and if B B were bored through and a pipe inserted rising up to the dotted line, as C O, the water would rise and stand at O. If there were no springs at S S, the space below the dotted line might still be filled with water rising from the stratum C C C; but if the boring took place at G the water would not rise, but on the contrary, if there were any on the surface, it would be carried down to the porous stratum E C C and run off. Thus in one situation boring will bring water, and in another it will take it off. This principle being well understood will greatly facilitate all draining of springs. Wherever water springs there must a be pervious and an impervious stratum to cause it, and the water either runs over the impervious surface or rises through the crevices in it. When the line of the springs is found, as at S S, the obvious remedy is to cut a channel with a sufficient declivity to take off the water in a direction across this line, and sunk through the porous soil at the surface into the lower impervious earth. The place for this channel is where the porous soil is the shallowest above the breaking out, so as to require the least depth of drain; but the solid stratum must be reached, or the draining will be imperfect. It was by attending to all these circumstances that Elkington acquired his celebrity in draining, and that he has been considered as the father of the system. It is however of much earlier invention, and is too obvious not to have struck any one who seriously considered the subject. In the practical application of the principle great ingenuity and skill may be displayed, and the desired effect may be produced more or less completely, and at a greater or less expense. The advice of a scientific and practical drainer is always well worth the cost at which it may be obtained.

When there is a great variation in the soil, and it is difficult to find any main line of springs, it is best to proceed experimentally by making pits a few feet deep, or by boring in various parts where water appears, observing the level at which the water stands in these pits or bores, as well as the nature of the soil taken out. Thus it will generally be easy to ascertain whence the water arises, and how it may be let off. When there is a mound of light soil over a more impervious stratum, the springs will break out all round the edge of the mound; a drain laid round the base will take off all the water which arises from this cause, and the lower part of the land will be effectually laid dry. So, likewise, where there is a hollow or depression of which the bottom is clay with sand in the upper part, a drain laid along the edge of the hollow and carried round it will prevent the water running down into it, and forming a marsh at the bottom.

When the drains cannot be carried to a sufficient depth to take the water out of the porous stratum saturated with it, it is often useful to bore numerous holes with an auger in the bottom of the drain through the stiffer soil; and, according to the principle explained in the diagram, the water will either rise through these bores into the drains and be carried off, and the natural springs will be dried up, or it will sink down through them as at c, in the section, if it lies above. This method is often advantageous in the draining of peat mosses, which generally lie on clay or stiff loam, with a layer of gravel between the loam and the peat, the whole lying in a basin or hollow, and often on a declivity. The peat, though it retains water, is not pervious, and drains may be cut into it which will hold water. When the drains are four or five feet deep and the peat is much deeper, holes are bored down to the clay below, and the water is pressed up through these holes, by the weight of the whole body of peat, into the drains, by which it is carried off. The bottom of the drains is sometimes choked with loose sand, which flows up with the water, and they require to be cleared repeatedly; but this soon ceases after the first rush is past, and the water rises slowly and gradually. The surface of the pit being dried, dressed with lime, and consolidated with earth and gravel, soon becomes productive. If the soil, whatever be its nature, can be drained to a certain depth, it is of no consequence what water may be lodged below it. It is only when it rises so as to stagnate about the roots of plants that it is hurtful.

When a single large and deep drain will produce the desired effect, it is much better than when there are several smaller, as large drains are more easily kept open and last longer than smaller; but this is only the case in tapping main springs, for if the water is diffused through the surrounding soil, numerous small drains are more effective. But as soon as there is a sufficient body of water collected, the smaller drains should run into larger, and these into main drains, which should all, as far as is practicable, unite in one principal outlet, by which means there will be less chance of their being choked up. When the water springs into a drain from below, it is best to fill up that part of the drain which lies above the stones or other materials which form the channel with solid earth well pressed in, and made impervious to within a few inches of the bottom of the furrows in ploughed land, or the sod in pastures; because the water running along the surface is apt to carry loose earth with it, and choke the drains. When the water comes in by the side of the drains, loose stones or gravel, or any porous material, should be laid in them to the line where the water comes in, and a little above it, over which the earth may be rammed in tight, so as to allow the horses to walk over the drain without sinking in.

It sometimes happens, that the water collected from springs which caused marshes and bogs below, by being carried in new channels, may be usefully employed in irrigating the land which it rendered barren before; not only removing the cause of barrenness, but adding positive fertility. In this case the lower ground must have numerous drains in it, in order that the water let on to irrigate it may not stagnate upon it, but run off after it has answered its purpose.

The third branch in the art of draining is the removal of water from impervious soils which lie flat, or in hollows, where the water from rain, snow, or dews, which cannot sink into the soil on account of its impervious nature, and which cannot be carried off by evaporation, runs along the surface and stagnates in every depression. This is by far the most expensive operation, in consequence of the number of drains required to lay the surface dry, and the necessity of filling them with porous substances, through which the surface water can penetrate.

It is very seldom that a field is absolutely level; the first thing, therefore, to be ascertained is, the greatest inclination and its direction. For this purpose there is an instrument essential to a drainer, with which an accurately horizontal line can be ascertained, by means of a plummet or a spirit-level. A sufficient fall may thus be found or artificially made in the drains to carry off the water. One foot is sufficient fall for a drain 300 feet in length, provided the drains be not more than 20 feet apart. It is evident that the drains cannot always be in a straight line, unless the ground be perfectly even. They should, however, never have sudden turns, but be bent gradually where the direction is changed. The flatter the surface and the stiffer the soil, the greater number of drains will be required. It is a common practice with drainers to run a main drain directly down the slope, however rapid, and to carry smaller drains into this alternately on the right and left, which they call herring-bone fashion. But this can rarely be approved of. It generally happens that, besides surface water, there are also some land springs arising from a variation in the soil: these should be carefully ascertained, and the drains should be so laid as to cut them off.

The following memoranda are suggestive of the principles which should guide practice on the subject; and may serve also to indicate directly what correct practice generally is:—

Food enters plants chiefly as dissolved in water. The relations of water to the plant and to the soil are therefore of the first importance. Water is a powerful solvent, extracting soluble matters from the air and from the soil through which it passes. The air in rain-water contains one half more oxygen, and three to six times more carbonic acid than the air of the atmosphere. Rain water also contains nitric acid and ammonia.

The contents of rain-water, its solvent powers exerted on the mineral and other matters useful as food for plants in the soil, and its relations to temperature, are the three points on which its fertilising influences depend.

Water gets into land in three ways: 1st, as rain falling on the surface; 2nd, as spring water; 3rd, by capillary attraction exerted on a wet subsoil.

Water leaves the land in three ways: 1st, by running off its surface; 2nd, by evaporating from its surface; 3rd, by percolating through its substance. In the first case it is wholly inoperative, except in so far as it does mischief by carrying off the finer surface particles of the soil either in solution or otherwise. In the second case it carries off, in great measure to waste, matters capable of evaporation, and useful as food for plants, which it holds in solution; but the most considerable result of evaporation is the loss of heat consequent upon it. As much heat as the burning of two or three ounces of coal could produce is lost by the evaporation of 1 lb. of water. Dalton's gauge indicated an annual evaporation of 24 inches out of 33 inches of an annual rainfall. Dickenson's gauge indicated an evaporation of 15 out of 26. During percolation through the land, which is the third way in which water leaves the soil, it introduces into the land the temperature of the air, it introduces atmospheric elements into the soil, it dissolves food out of the land and carries it to the roots of plants.

The principal practical benefit derived from drainage is the easier and cheaper cultivation of which drained land is capable. The greater fertility of such land is in a measure due to the whole substance of it, its whole internal surface being brought under the influence of air and rain-water.

The object of drainage then is to induce the percolation of rain-water through the soil. To this end conduits are laid under ground at such a depth and at such intervals as experience finds sufficient. And the points connected with the practice to be considered are (1), the depth, as limited by the outfall, as desirable in the interests of fertility, and as necessary owing to the constitution of the soil; (2), the frequency and capacity of the drain to correspond with the rain-fall and, with the character of the soil; (3), the arrangement of the drains, uniform to correspond with the uniformity of the supply in rain, or irregular to correspond with the subsequent irregular distribution of the rain-water throughout the soil.

(1). As to depth—its principal limit is cost—that it should be considerable is desirable on the ground of the greater depth of material being thus fertilised and made useful to the plant. Drains 2 and 3 and 4 feet deep may, other things being equal, cost *3l.*, and *4l.*, and *5l.* per acre—but there are thus brought into use 18, 30, and 42 hundred tons of earth per acre, which is after the rate of 600, 700, and 800 tons for every pound of expenditure—so that the deeper and costlier drain may be the cheaper in the end. But depth is regulated to some extent by the capillary attraction of the soil upon the water which it holds, a considerable height of column to give the weight necessary to force that attraction being required.

(2). The frequency of drains must be greater according to the greater quantity of water falling in a given time as rain, to which the climate exposes the land to be drained, and according to the difficulty of percolation which the land presents. In practice the quantity of exit provided in the least efficient drainage is sufficient for the removal of the largest probable rain-fall. The size of the pipes is determined by other considerations than the quantity of water they have to deliver—a larger pipe is rendered desirable by the fact that when a smaller one is used a very slight displacement breaks the continuity of the pipe.

The interval between drains is to be determined by the rain-fall and the capability of percolation. The depth of drains should be allowed very little influence on the interval. The direction of drains should be right down the slope, simply because when once the water gets into them, the shortest way out of the field is the best.

(3). The arrangement of the drains at varying intervals is necessary sometimes, to suit the varying distribution by which rain-water is accumulated in certain spots, so that springs and swamps are produced.

As a general rule, however, drains as nearly 4 feet deep as may be, and from 5 to 10 yards apart,—greater according to the porosity of soil and subsoil, should be laid parallel to one another, and for the most part straight down the slope. The material used should be the common cylindrical pipe tile, about 2 inches in the bore, less than this at the upper part of the drain, more in the lower.

In commencing drainage, prepare a general plan for the farm or estate. Seek, in the first place, by straightening water-courses and draining springs, to give rapid exit for all the water that comes into the land otherwise than from the clouds. In the after drainage of the land the general rule is to commence the drainage of the lowest part first, attending to the final outfall first of all. There are exceptional cases where the drainage of a higher land may to some extent remove water at once which fed the lower grounds. When spring water is removed, drain as deep (to 4 feet) as the outfall will permit, and with such attention to uniformity of interval as the adhesiveness or porosity of the soil shall indicate. Notwithstanding the outcry against rules and systems in drainage—uniformity of interval *is* the rule, and the so-called "gridiron" system is the safest; departures from either being exceptional.

Before carrying out the system however let all such obstacles and nuisances (crooked hedge rows, old ditches, and timber) as it is intended to remove be removed.

Trial holes are useful to determine the interval which may be desirable between the minor drains. Ascertain the experience of your neighbours on this point. Widen the interval, because the soil admits of the more easy percolation of the water, not because you have made your drains deeper.

The cost of digging 4 feet deep drains 1 foot to 14 inches wide at top to receive a 2-inch pipe at bottom may be from 6*d.* per rod of 5½ yards in homogeneous clays to any greater sum when the pickaxe may be needed. The following Table is taken from Bailey Denton's pamphlet on the subject.

Cost of Drainage, per acre, 4 feet deep (Denton).

(1) Labour of cutting and filling in.
(2) Material—pipes at 18*s.* to 20*s.* a 1000.
(3) Haulage, 2*s.* 6*d.* per 1000.
(4) Pipe laying and finishing, 1*d.* per rod.
(5) Superintendence.
(6) Extra for mains.
(7) Iron outlet pipes and masonry.
(8) Collars if used.

Mains may require 4-inch pipes at the outfall, gradually smaller near the upper end. A long minor drain may need 1, 1½, and 2-inch pipes as you approach its junction with the main. Its water should *fall* into the main pipe, and the junction should be with a curve, not abruptly. Open ditches should be avoided if possible. When necessary their sides should slope with a fall of from 1 in 1 to 1 in 2, according to the material. They are necessary as a preliminary drainage in peat soils and bogs. Small open ditches (15 inches deep or so) laid with a regard to local outbreaks of water, are a great and cheap (1½*d.* per rod) improvement of mountain pasture. Drain stoppages arise very rarely from direct infiltration, generally either by the growth of root fibres, or the formation of peroxide of iron in the drain water. The remedy for the former is extra depth, and care for the joints where the danger is great, and for the latter thorough cultivation by which iron may be peroxidised in the soil, not in the water which drains out of it. A uniform slope in the drains tends to diminish the risk of stoppage, and a small pipe (if large enough) is better than a large one.

Whatever system of drainage be adopted, see that it be thoroughly done. "Nothing is stronger than its weakest part," and a defective patch may check the cultivation of the whole field. Subsoil ploughing across the drainage tends to its immediate and increased efficiency.

In draining fields it is usual to make the outlets of the drains in the ditch which bounds them. The fewer outlets there are, the less chance there is of their being choked; they should fall into the ditch considerably above the bottom, and a wooden trunk, or one of stone, should be laid so that the water may be discharged without carrying the soil from the side of the ditch. If there is water in the ditch, it should be kept below the mouth of the drain. The outlets of all drains should be repeatedly examined, to keep them clear; for wherever water remains in a drain, it will soon derange or choke it. The drains should be so arranged or turned that the outlet shall meet the ditch at an obtuse angle towards the lower part where the water runs to. A drain brought at right angles into a ditch must necessarily soon be choked by the deposition of sand and earth at its mouth.

As the draining of wet clay soils is the only means by which they can be rendered profitable as arable land, and the expense is great, various instruments and ploughs have been contrived to diminish manual labour and expedite the work. Of these, one of the simplest is the common mole-plough, which in very stiff clay makes a small hollow drain below the surface, by forcing a pointed iron cylinder horizontally through the ground. It makes a cut through the clay, and leaves a cylindrical channel, through which the water which enters by the slit is carried off. It requires great power to draw it, and since steam-power has been used for the purpose, strings of pipe-tiles have been drawn in behind the "mole," so as to leave permanent tunnels or conduits at any required depth beneath the surface.

But a draining-plough has been invented which, assisted by numerous labourers, greatly accelerates the operation of forming drains, by cutting them out in a regular manner, when they are immediately finished with the usual tools and filled up. It has done wonders in some of the wet stiff soils in Sussex, and is much to be recommended in all wet and heavy clays. In stony land it cannot well be used. The subsoil plough, introduced to public notice by Mr. Smith of Deanston, may be considered in some measure as a draining-plough, for it loosens the sub-soil, and facilitates the drainage of the land. By means of judicious drains and the use of the subsoil plough, the stiffest and wettest land may in time become the most fertile.

The tools used in draining are few and simple. Spades, with tapering blades of different sizes, are required to dig the drains of the proper width, and the sides at a proper angle. Hollow spades are used in very stiff clay. When the drains begin to be very narrow near the bottom, scoops are used, of different sizes, which are fixed to handles at various angles, more conveniently to clear the bottom and lay it smooth to the exact width of the tiles, if these are used; for the more firmly the tiles are kept in their places by the solid sides of the drain, the less likely they are to be moved.

DRAM, or DRACHM, a small measure of weight, the etymology of which is to be found in the Greek drachma (δραχμή). The dram of our pound troy is stated to be nearly the same as the Attic drachma, or the Roman denarius (under the earlier emperors).

There are two drams remaining in our system of weights; the first is the sixteenth part of the ounce, which is the sixteenth part of the pound avoirdupois of 7000 grains; this is now totally out of use, as no species of goods which are weighed by the avoirdupois weight are of such value as to make the sixteenth part of an ounce worth consideration. In the national standard, the troy pound of 5760 grains, there is no dram; but this weight occurs in that particular division of the troy pound which is used by apothecaries, in which the dram is the eighth part of the ounce, which is the twelfth part of the pound of 5760 grains. This is the real remnant of the Roman division; the denarius (which, according to Pliny, was the Attic drachma of his time) was, however, the *seventh* part of the ounce. The dram is used in England, France, Holland, Prussia, Turkey, and in some parts of the Levant.

DRAMA; DRAMATIC LITERATURE. A complete history of the drama would be almost equivalent to a history of civilised society over the greater part of the earth. Nearly every ancient as well as every modern civilised people, except perhaps the ancient Egyptians, seem to have possessed some kind of dramatic representation. The Hindus have a rich store of dramatic works, extending back to a very remote period. The Sanskrit drama of Sakontala, well translated by Mr. Eastwick, though very beautiful, is not fitted for any stage representation, and in recent times it has had few imitators. The Chinese, according to Sir J. F. Davis ('The Chinese; a general description of the Empire of China and its Inhabitants,' vol. ii.) have a rage for theatrical exhibitions. In their dramas they disregard the unities, depend not at all on scenic effect, divide them into five acts, or rather an introduction and four "breaks," and use rhymes and music. Several of their dramas have been translated into French, English, and German. They show customs and manners, rather than depict characters, and the plots are often ingenious. In this summary we shall not enter into any examination either of the ancient or the existing oriental drama. Notwithstanding the great extent and fertility, the vast population and industry of those remoter Asiatic regions, the spirit of their social institutions, to whatever moral causes originally owing, seems to doom them (external influences apart) to a perpetual stationariness, excluding them as it were from the history of general civilisation, which is essentially the history of progress.

The Attic drama (δρᾶμα, an action), is said by Aristotle ('Poet.' iv., 14) to have arisen from the recitations of the leaders of the DITHYRAMBUS. To understand this statement we must bear in mind that a Greek tragedy always consisted of two distinct parts; the dialogue which was written in the Attic dialect, and corresponded in its general features to the dramatical compositions of modern times, and the chorus, which to the last was more or less pervaded by Dorisms, and the whole tone of which was lyrical rather than dramatical. We must add that the metre of the dialogue, whether Iambic or Trochaic, was staid and uniform while the choruses were written with every variety of metre. In a word, the dialogue was meant to be recited; the chorus was intended to be sung. It is obvious that these two elements must have had different origins. The one was an offshoot of the lyric poetry which sprung up among the Dorians, the other is to be referred to the rhapsodical recitations which were peculiar to the Ionian branch of the Greek nation; and as the Athenians stood in the middle between the Ionians and the Dorians, so the Attic drama may be considered as the point of intersection of the Ionian and Dorian literatures. That choral and consequently lyrical poetry should spring up among the Dorians was a natural result of the peculiar organisation of a Doric state: and the Epos as naturally arose among the Ionians, the countrymen of Homer. ('Hist. of the Literature of Greece,' by Müller, continued by D. Donaldson.) [Homer, in Biog. Div.] The Ionian epic poetry, which was written in dactylic hexameters, was recited by a set of men called *rhapsodists* [Rhapsody]; and the gnomic and didactic poetry of Hesiod was recited in the same way. But the dactylic hexameter was not found suitable for gnomic poetry, and a modification of it, consisting also of six feet, but each foot shorter by a half-time than the dactyl, was substituted for it. This metre (the Iambic), or a lengthened form of it (the trochaic), was used by Archilochus, Simonides of Amorgus, and Solon, whose verses were recited by themselves or by rhapsodists in the same way as the epic poetry which preceded them.

The lyric poetry of the Dorians was originally appropriated to the worship of Apollo, but the particular odes and choruses used in this worship were in process of time transferred to Dionysus [Dionysus]; and these odes and choral dances had, all of them, their representatives in the dramatic poetry of a later age. (Athenæus, p. 630, d.) But the Dithyrambus was the earliest species of choral poetry connected with the worship of Dionysus, and it appears from many allusions, and indeed from Dithyrambic fragments, that while the body of the song was composed in irregular metres, the poet himself, or some rhapsodist, acting as exarchus, or leader, in his place, recited trochaics as an introduction. Here then was a mixture of recitation and chorus perfectly analogous to the tragedy of later time, which was probably suggested by it; and it is in this sense, we doubt not, that Aristotle attributes to the leaders of the Dithyrambus the origin of tragedy.

We read of a lyrical tragedy long before Thespis, and this appears to have been a modification of the Dithyrambus with a lyrical accompaniment instead of the flute-music to which it was originally danced, and with a substitution of men dressed as satyrs for the usual chorus, which alteration is attributed to Arion. The union of this lyrical tragedy with the recitations of rhapsodists is said to have been brought about by Thespis, a contemporary of Pisistratus and Solon, and may have been suggested as well by the recitations of the leaders of the Dithyrambus as by the union of rhapsodical recitations with the Dionysian rites. Thespis introduced one actor, an exarchus, or rhapsodist, who, standing on an elevated place, while the dithyrambic chorus were grouped around the altar of Dionysus, carried on a dialogue with them, or narrated some mythical story in character. The comedy of ancient Greece originated in the festival of the vintage, when the country people went from one village to another, in carts or on foot, and indulging in rude jests and coarse invectives. From these effusions comedy was developed either in Megaris or in Sicily. Its first approach to perfection was owing to the genius of Epicharmus, who is said by Plato ('Theætet.' p. 152, e) to have borne the same relation to comedy that Homer did to tragedy. A similar comic drama sprung up about the same time at Athens, and was carried to a wonderful degree of strength and beauty.

The dramas of ancient Greece were always performed at and as a part of the festival of Dionysus [Dionysia]. The plays for exhibition had previously been submitted by their authors to a board of judges, and approved by them.

Æschylus, the true father of the Attic drama (so far at least as we are acquainted with it), was born in Attica about the year b.c 525, and died probably about b.c. 456, having survived the splendid victories of Salamis, Platæa, and Mycale. Thus he may be said to have flourished during the vigorous youth of Athenian liberty and glory.

There are three grand characteristics of tragedy as conceived by Æschylus, that distinguish it widely from the serious drama of modern times. These are, 1. The religious tone which pervades it throughout; 2. The ideal nature of the whole representation; 3. The large part in the composition still assigned to the lyric muse. These three matters we shall endeavour to place in a clear light before the reader, as upon a knowledge of them mainly depends the capability to form something like an accurate notion of the distinctive character of Grecian tragedy.

First, as regards the religious complexion of the Athenian drama. Modern readers, familiarised from their infancy with the names, attributes, and images of the ancient deities, merely as presenting an inexhaustible storehouse of graceful poetic ornament, almost inevitably forget, in turning to peruse any original work of the ancients, that, how much soever their philosophers, their poets, or their priests, might regard their principal divinities in a purely symbolical view, yet that to the minds of the people at large they were real and awful existences, having will, passions, and various kinds and degrees of dominion over the fortunes and the happiness of man. This important fact has not been sufficiently taken notice of in modern accounts of the ancient drama. All the deities, male or female, celestial or infernal, were objects of fear and propitiation: only the inexorable Fates were unappeasable by god or man. Fate, indeed, was the only omnipotence recognised in the mythological system of the Greeks; for Jupiter himself, the ruler of the celestial deities, the sovereign of Olympus, was regarded neither as eternal nor as infinite in power. Nowhere have poetry and her sister arts been more thoroughly devoted to the service of religion than they were in ancient Greece. Thus we find the drama itself lying in embryo in the worship of Dionysus; and when in its maturity it lost the direct character of a religious rite, we shall find the sacred character impressed on tragedy even more solemnly than upon any of the other productions of Athenian genius not primarily devoted to religious objects.

The *ideality* of the scenic representation, as arranged by Æschylus, necessarily resulted from the adoption, in the composition of the drama, of ideal and of nearly ideal characters. "The use of masks," observes Schlegel, "which appears astonishing to us, was not only justifiable on this principle, but absolutely essential; and far from considering them in the light of a last resource, the Greeks would justly have considered as a last resource the being obliged to allow a player with vulgar, ignoble, or strongly marked individual features, to represent an Apollo or a Hercules. To them this would have appeared downright profanation. . . . . As the features of the player acquired a more decided expression from the mask, as his voice was strengthened by a contrivance for that purpose, so also the *cothurnus*, which consisted of several considerable additions to his soles, as we may see in the ancient statues of Melpomene, raised his figure considerably above the middle standard. The female parts, too, were played by men, as the voice and other qualities of women would have conveyed an inadequate idea of the energy of tragic heroines. The forms of the masks and the whole appearance of the tragic figures, we may easily suppose, were sufficiently beautiful and dignified. We should do well to have the ancient sculpture always present to our minds; and the most accurate conception, perhaps, that we can possibly have, is to imagine them so many statues in the grand style, endowed with life and motion. But as in sculpture they were fond of dispensing as much as possible with dress, for the sake of exhibiting the more essential beauty of the figure; on the stage they would endeavour, from an opposite principle, to clothe as much as they could well do, both from a regard to decency, and because the actual forms of the body would not correspond sufficiently with the beauty of the countenance. They would also exhibit their divinities, which in sculpture we always observe either entirely naked or only half covered, in a complete dress. [We would remark, however, that the *early* Greek statues of divinities were always clothed. It was only when sculptors, thinking to philosophise their art, ventured to treat their deities as means for exhibiting ideal beauty of form, that the figures became nude.] They had recourse to a number of means for giving a suitable strength to the forms of the limbs, and thus restoring proportion to the increased height of the player.

Greek Theatrical Masks.

"The great breadth of the theatre, in proportion to its depth, must have given to the grouping of the figures the simple and distinct order of the bas-relief. . . . . The gestures accompanied the rhythmus of the declamation, and were intended to display the utmost beauty and harmony."

In the syllabic composition, which then at least prevailed in the Grecian music, the solemn choral song had no other instrumental accompaniment than a single flute, which could not impair the distinctness of the words. The choruses and lyrical songs in general form the portion most difficult to understand of the ancient tragedy, and must also have been the most difficult to contemporary auditors. They abound with the most involved constructions, the most unusual expressions, and the boldest images and allusions. Such labour and art would hardly have been lavished upon them by the poets merely to be lost in the delivery. Such a display of ornament without aim is very unlike the mode of thinking of the Greeks. In the syllabic measure of their tragedy there generally prevails a highly finished regularity, which, however, by no means appears a stiff symmetrical uniformity. Besides the infinite variety of the lyrical strophes, they have also a measure to denote the mental transition from the dialogue to the lyric, the anapæst; and two for the dialogue itself, of which the one by far the most general, the iambic trimeter, denoted the regular progress of the action, and the other, the trochaic tetrameter, was expressive of sudden passion. Indeed, the simplicity of the Greek tragedy, of which so much has been said, attaches only to the plan; for the richest variety of poetical ornament is observable in the execution. It must be remembered, too, that the utmost accuracy in the delivery of the different modes of versification was expected from the player, as the delicacy of the Grecian ear would not excuse, even in an orator, the false quantity of a single syllable.

But the epic form, under which their greater and more national compositions present themselves to us in their earlier times, had, for a long period before the rise of the dramatic art among them, been rivalled by the lyric; and many old subjects of high heroic song had been embodied under a new shape in grand choral compositions, which, observes Mr. Thirlwall ('Hist. of Greece,' chap. xii.) "uniting the attractions of music and action with those of a lofty poetry, formed the favourite entertainment of the Dorian cities. This appears to have been the germ out of which, by the introduction of a new element, the recitation of a performer who assumed a character, and perhaps from the first shifted his mask so as to exhibit the outlines of a simple story in a few scenes parted by the intervening song of the chorus, Thespis and his successors gradually unfolded the Attic tragedy."

Such being the firmly established practical circumstances of Greece, a transition all at once from the combined epic and lyric forms to the purely dramatic was, we conceive, neither practicable even to a genius of the first order, as we admit Æschylus to have been, nor very likely even to enter into his imagination. Æschylus by no means introduced the chorus into the drama: he may be much rather said to have introduced the drama into the chorus; and that of itself was no slight achievement. We have already remarked, that the idea of any great public exhibition unaccompanied by choral songs was one into which the Greek taste and imagination of that day could by no means enter. So strong, however, was the bent of Æschylus towards the dramatic, that he not only retains the chorus as a lyrical accompaniment, but gives it also a participation in the action itself. This, in stamping the dramatic character upon the whole performance, was as far as he could venture to go, and, as we have already said, was most likely as far as he desired to go.

We must now, in order to complete the idea which we desire to present of the material forms of the Grecian drama, give a short account of the architectural structure and arrangement of the edifice itself in which the pieces were exhibited, when once, under the hand of Æschylus, their dramatic element was distinctly developed. Brief as we shall endeavour to make this description, some detail is indispensable, owing to the very different plan from the modern upon which the whole conception and design of the ancient drama required that its theatres should be constructed.

The theatres of the Greeks were open to the sky, and their dramas were always acted during the day,—a mode of construction and of exhibition which was highly favoured by the beauty of their climate. As regards the inconvenience which many modern critics have supposed the poets to have felt, from the necessity of always laying the scene of their pieces before houses, and thus often violating probability, it should be observed that the Greeks lived much more in the open air than we do, and transacted many things in public places which with us usually take place in houses; and the stage did not represent a street, but a space before the house and belonging to it, wherein stood an altar on which the sacrifices to the household gods were offered up. Here the women (who among the Greeks lived in so retired a manner) might appear without impropriety, even the unmarried ones. Neither was it impracticable to give a view of the interior of the houses: this was done by means of the encyclema, which we shall presently describe.

The Grecian theatres, destined, not like those of the moderns, for a long succession of daily exhibitions, but for the celebration of a few annual festivals, were of that colossal magnitude which was indispensable to contain, as it were, the whole body of the people, together with the concourse of strangers who flocked to these solemnities. The distance to which the eyes of the spectators were thus necessarily thrown from the acted scene presents another obvious reason for and justification of the artificial expansion, as we may term it, of the whole figure of the actor. The groups on the stage, not to appear absolutely insignificant, needed, if possible, to be represented larger than life; and besides the fundamental reason which we have already stated for the constant use of the mask, that play of the actor's features which it concealed could not have been perceived with any distinctness across the vast space which separated him from the audience. Analogous to the use of the mask, the buskin, &c., were certain contrivances for increasing the loudness of the voice. Vitruvius tells us also of vehicles of sound distributed throughout the building; and though of these we have no very clear account, we may safely assume that the theatres of the ancients were constructed on very perfect acoustical principles. We know from existing remains that all who were present at the dramatic exhibition could be, in the literal sense of the word, spectators. The seats for them consisted of steps rising backwards round the semicircle of the orchestra, the name given to the whole internal area called in a modern theatre the pit. The lowest step of this amphitheatre was raised considerably above the orchestra, and opposite to it was the stage, placed at an equal elevation. The sunk semicircle of the orchestra contained no spectators, but served another purpose, which we shall shortly have to mention. The stage consisted of a strip, which, forming the chord of the semicircle, extended from one end of the building to the other, but the depth of which bore little proportion to this length. This was called the logeum, or, in Latin, pulpitum, and the usual place for the dramatic action was in the middle of it. Behind this middle part the scene receded quadrangularly; still, however, with less depth than breadth: the space thus comprised was called the proscenium. The remaining part of the logeum, to the right and left of the scene, had, both in front on the verge of the orchestra and at the back, a wall entirely plain, or at most architecturally ornamented, which rose to the level of the uppermost seat for the spectators.

The decoration was so contrived that the principal object in front covered the back-ground, and the prospects of distance were given at each side, which is just the reverse of the mode adopted on the modern stage. This was done according to certain rules: on the left appeared the town to which the palace, temple, or whatever occupied the centre belonged; on the right was the open country, landscape, mountains, sea-shore, &c. The lateral decorations were three-sided constructions turning on a pivot fixed underneath, by which means the changes of scene were partly effected. In the back decoration it is probable that many things were exhibited substantially which with us are only painted. When a palace or temple was represented, there appeared in the proscenium an altar, which answered a number of purposes in the course of the performance. The central decoration was most frequently architectural, though sometimes it was a painted landscape; and from a passage of Plato it seems clear that the Greeks must have carried theatrical perspective to very considerable perfection.

In the back wall of the scene were a large main entrance and two side ones; and as the hinder decoration was generally a palace in which the principal characters of royal descent resided, they naturally came through the great door, and the servants made their entrance from the wings. There were two other entrances; one at the end of the logeum, whence the inhabitants of the town came; the other in the orchestra below, for characters who were supposed to come from a distance; they ascended the logeum by a staircase from the orchestra, which was applicable to a variety of purposes, as circumstances required. The situation of these several entrances explains many passages in the ancient dramas, where the persons standing in the middle see some one advancing long before he comes near them. Beneath the seats of the spectators a stair was somewhere constructed through which the spectres of the departed, unperceived by the audience, ascended into the orchestra, and thence, by the staircase above mentioned, made their appearance on the stage. The nearest verge of the logeum sometimes represented the sea-shore. The Greeks were well skilled also in availing themselves, for scenic effect, even of what lay beyond the decorations. The frequent addresses to heaven were doubtless directed to the actual skies; and it was a general principle with them, that everything imitated on the stage should, if possible, consist of actual representation, and only where this could not be done were they content with a symbolical exhibition. The machinery for the descent of gods to the earth or the withdrawing of men from it, was placed aloft behind the wall at each side of the scene, and so removed from the sight of the audience. There were hollow places beneath the stage, and contrivances for thunder and lightning, for the apparent fall or burning of a house, &c. An upper story could be added to the farthermost wall of the scene, when it was necessary to represent a tower having an extensive prospect, &c. The encyclema was a machine semicircular within, and covered above, which represented the objects contained in it as in a house; this could be thrust behind the great middle entrance, and we find it to have been so used for the production of a grand theatrical effect, the central entrance being then left open to exhibit the interior to the audience. A stage curtain is mentioned both by Greek and Roman writers; indeed its Latin appellation, *aulæum*, is borrowed from the Greeks. It seems, however, not to have been in use in the earlier period of the Attic theatre; and when brought into use it covered, not the whole length of the logeum, but only the comparatively small front of the proscenium.

The entrances for the chorus were beneath, in the orchestra, in which it generally remained, and in which it performed its solemn dance, moving round first in one direction, then in the other, during the choral songs. In front of the orchestra, opposite to the middle of the scene, was an elevation with steps, resembling an altar, raised to the level of the stage, and called the thymele. This was the station of the chorus when it did not chant, but was taking an interest in the action. The leader of the chorus then took his or her station on the top of the thymele, to see what was passing on the stage, and to communicate with the characters. For though the choral song was common to the whole, yet when it entered into the dialogue, one of its number spoke for the rest, which accounts for the changing from the plural number to the singular, and *vice versâ*, in addressing them from the stage. The thymele was situated precisely in the centre of the building, and all the measurements were calculated from that point.

It is plain that the Grecian theatre, both in its architectural and its scenic arrangements, must have attained much higher perfection in the course of that illustrious period of Grecian art which we are accustomed to denominate, from its most characteristic and influential name, the age of Pericles, than it had reached at the termination of the dramatic career of Æschylus. The very building itself, which in the general and splendid restoration of Athens after the termination of the Persian war, was reconstructed of massive stone, was originally of timber only. Of the works of the three great masters of the Greek tragedy, Æschylus, Sophocles, and Euripides, a particular account is given under their respective names in the Biog. Div.

We shall, perhaps, form the best idea of the old Grecian comedy by considering it as a complete contrast to the ideal tragedy. Although the old comic writers gave the names of existing persons to their characters, they did not exhibit them on the stage with all the circumstances peculiar to certain individuals; for such historical characters have always with them an allegorical signification; they represent a class; and as their features were exaggerated in the masks, so their characters were overcharged in the composition. Still this constant allusion to the nearest reality, which not only allowed the poet, in the character of the chorus, to converse with the public in a general way, but also to point at certain individual spectators, is of essential import in any view of this species of composition. As the spirit of the elder tragedy delighted in harmonious unity, the old comedy, on the contrary, flourished in a chaotic exuberance, seeking out the most glaring and diversified objects, the most strongly marked oppositions, working up the most singular, unheard of, and even impossible adventures, with the local peculiarities nearest at hand. The comic poet, indeed, as well as the tragic, transported his characters to an ideal element; not, however, to a world subjected to Necessity, but to one where the caprice of an inventive wit prevails without restraint, and all the laws of reality are suspended.

Comedy, in the hands of its Doric founder Epicharmus [Epicharmus, in Biog. Div.], borrowed its materials chiefly from the mythical world. Nor in its maturity did it altogether relinquish that field, as appears from the titles of many of the lost pieces of Aristophanes and his contemporaries. But as a violent contrast between the materials and the form is here quite appropriate, the subjects of the old comedy were naturally drawn from the most serious concerns of public life and the state: the private and family life was only introduced occasionally, and indirectly, with a reference to the public. The chorus, besides that it was essential to the complete parody of the tragic form, also contributed to the expression of that festal gladness of which comedy was the most unrestrained effusion; for, as already observed, in all the popular and religious festivals of the Greeks choral songs were chanted, accompanied by dancing. On some of these occasions we find in the comic chorus such a display of sublime lyrical poetry that the passages might be transferred to tragedy without alteration. It is, however, one deviation from the tragic model, that often there are several choruses in the same comedy, who at one time all sing together and in opposite positions, and at other times change with and succeed each other without any general reference. But the most remarkable peculiarity of the comic chorus is the *parabasis*, an address by the chorus to the spectators, in the name and under the authority of the poet, which has no immediate concern with the subject of the piece. Herein he sometimes enlarges on his own merits, and ridicules the pretensions of his rivals; at other times he avails himself of his privileges as an Athenian citizen, to deliver proposals of a serious or a ludicrous nature for the public good. The parabasis may have owed its invention partly to the circumstance of the comic poets not having such ample materials as the tragic to fill up the intervals of the action, when the stage was empty, with affecting and inspired poetry. But this very departure from the strictness of dramatic form is consistent with the essence of the old comedy; just as an individual, while wearing a droll disguise may, in the same spirit of drollery, venture occasionally to put aside the mask.

Of the Grecian comic writers of the old kind there is but one of whom any work has descended to us, so that in judging of his merits we can have no aid from comparison with other masters. Aristophanes had many predecessors, Magnes, Cratinus, Crates, and others; he was indeed one of the latest comic authors of that school, as he survived even the old comedy itself. This writer, the very singularity of whose escape from the general wreck of the elder comic productions renders him so interesting and valuable to the history of dramatic art, has been very erroneously judged of in latter times, owing to two capital defects in the mode in which modern criticism has been applied to him, namely, the want of sufficiently understanding the spirit of Athenian society of that day in general, and yet more, the want of a just view of what constituted the essential character of the old comedy itself. [Aristophanes, in Biog. Div.]

Towards the end of the Peloponnesian war, when a few individuals, violating the constitution, had assumed supreme authority in Athens, a law was enacted empowering any person attacked by comic poets to bring them to justice; and a prohibition was issued against introducing real persons on the stage, or using masks which bore a resemblance to their features, &c. This measure put a violent and final termination to the genuine old comedy. For a short time after, the endeavour was made to continue the existence of this ideal species under the political restrictions thus imposed; but these shackles were soon found to be fatal to its spirit and popular attractiveness; and this transitional kind, which has since been commonly designated as the middle comedy, soon gave way to the introduction of the new comedy, which, like the later Greek tragedy already mentioned, aimed at presenting a poetic mirror of actual life.

Although the new comedy developed itself only in the brief interval between the end of the Peloponnesian war and the first successors of Alexander the Great, yet the stock of pieces in this kind amounted to some thousands; time, however, has made such ravage among them that nothing remains to us but a number of detached fragments in the original language, often so disfigured as to be unintelligible, besides about twenty translations or copies of Greek originals in Plautus and six in Terence.

The Greek theatre, as we have seen, was originally constructed for the exhibition of the higher walks of the tragic drama; its stage was open to the sky, and exhibited but little of the interior of the houses. Comedy was therefore under the necessity of laying the scene out of doors; and had often to make people come out of their houses to confide their secrets to each other in the streets. It is true that the poets were thus spared the necessity of changing the scene, as it was taken for granted that the families concerned in the action lived in the same neighbourhood; besides that the Greeks, like all other southern nations, lived much more in the open air than we do. The chief disadvantage in this construction of the stage is, the circumscription of the female parts. If the actual manners were to be observed, as the essence of the new comedy required, the secluded life of the fair sex in Greece rendered the exclusion of unmarried women, and of young women in general, inevitable. No females could appear but aged mothers, maid-servants, or courtesans. Hence, besides the necessary sacrifice of so many agreeable situations, this other inconvenience is produced, that the whole piece frequently turns on a marriage with or a passion for a young woman whom the audience never once see from the beginning to the end of it.

The Romans, whose drama immediately follows that of the Greeks, were not led to the invention of theatrical amusements from the want of representations to fill up the leisure of their festivals, and enliven the mind by withdrawing it from the concerns of life; but, in the despondency of a desolating pestilence, against which all remedies seemed insufficient (year of Rome, 391), they had, according to the story, recourse to the theatre as a means of appeasing the anger of the gods, having previously been acquainted only with gymnastic exercises and circus races. The *histriones*, for whom they sent to Etruria, were however merely dancers, who probably did not attempt pantomimic movements, but strove to delight their audience by a display of bodily activity. The oldest spoken plays, the 'Fabulæ Atellanæ,' were borrowed by the Romans from the Osci, the indigenous inhabitants of Italy. [Atellanæ.] They were satisfied with these amusements till Livius Andronicus, somewhat more than 500 years after the foundation of Rome, began the imitation of the Greeks; and the regular compositions of tragedy and the new comedy (the old it was impossible to transplant) were then, for the first time, known in Rome. Thus the Romans owed the first idea of a play to the Etrurians, the effusions of a sportive humour to the Oscans, and the higher class of dramatic productions to the Greeks. They displayed, however, more originality in the comic than in the tragic department.

The Romans had, besides, their peculiar *mimi*. Their foreign name for these small pieces might lead us to conclude that they bore a great affinity to the Greek mimi; however, they differed considerably in form: we know also that the manners portrayed in them had a local truth, and that the subject was not derived from Grecian compositions. The later Greek mimi were dialogues in prose, yet written with a kind of rhythm, not designed for the stage; the Roman were in verse, were represented, and often delivered extempore. Their most celebrated authors in this way were contemporary with Julius Cæsar. These were, Laberius, a Roman knight, and P. Syrus, his freedman and scholar in the mimetic art. Not one of their compositions has descended to us entire. We have, however, a number of sentences from the mimi of Syrus, which, from their internal worth and elegant conciseness of expression, deserve to rank with those of Menander. One entire mimus, which unfortunately time has not spared for us, would have thrown more light upon the question than all the confused accounts of the grammarians, and all the conjectures of modern scholars.

The regular comedy of the Romans was for the most part *palliata*, that is, it appeared in a Grecian dress, and represented Grecian manners. This is the case with the whole of the comedies of Plautus and Terence. [Plautus and Terence, in Biog. Div.] But they had also a *comœdia togata*, so called from the Roman dress which was worn in it. Afranius is celebrated as the principal writer in this department. We have no remains whatever of him; and the accounts of the nature of his works are so very scanty, that we cannot even determine, with certainty, whether the togatæ were original comedies of an entirely new invention, or merely Greek comedies adapted to Roman manners. The latter supposition is the more probable, as Afranius lived in a period when the Roman genius had not yet attempted to soar on the wings of original invention; and yet we cannot well conceive the possibility of adapting Attic comedies, without the most violent constraint, to local circumstances of so very different a nature. The Roman way of living was in general serious and grave, though in private society they showed a great turn for wit and joviality. The diversity of ranks among them was politically marked in a very decided manner, and the wealth of private individuals was frequently not inferior to that of sovereigns; women lived much more in society, and acted a much more important part than among the Greeks, through which independence they fully participated in the overwhelming tide of corruption, and the external refinement by which it was accompanied. With these essential differences in the social system, an original Roman comedy would have been a most interesting phenomenon, and would have enabled us to view those conquerors of the world under an aspect altogether new. That this however was not accomplished in the *comœdia togata*, the indifferent manner in which it is mentioned by the ancients will hardly leave us room to doubt. Quintilian himself tells us in plain terms that the Latin literature was lamest in comedy.

With respect to tragedy, it must first of all be observed that the Grecian theatre was not introduced into Rome without considerable changes in its arrangement; that the chorus no longer had a place in the orchestra (wherein the most distinguished spectators, the senators and knights, now sat), but remained on the stage itself. At the very introduction, too, of the regular drama, Livius Andronicus, a Grecian by birth, and the earliest tragic poet and actor of Rome, in the monodies (lyrical pieces chanted by a single person, and not by the chorus), separated the singing from the mimetic dancing, so that the latter alone remained to the actor; and instead of the former, a boy stood beside the flute-player, and accompanied him with his voice. Among the Greeks in better times, the tragic singing and the accompanying rhythmical gestures were so simple, that one person was sufficient to do at the same time the most ample justice to both. The Romans, however, it would seem, preferred separate skill to harmonious unity. Hence arose their fondness, at an after period, for pantomimes, of which the art was, in the time of Augustus, carried to the greatest perfection. From the names of the most celebrated of the performers, Pylades, Bathyllus, &c., it would appear that those who practised this mute eloquence in Rome were Greeks; and the lyrical pieces which their dancing expressed were also delivered in the Grecian language. Roscius frequently played without a mask, and in this respect probably did not stand alone; but so far as we know, there never was any such instance among the Greeks.

In the tragic literature of the Romans there are two epochs: the first is that of Livius Andronicus, Nævius, Ennius, and also of Pacuvius and Attius, who both flourished somewhat later than Plautus and Terence; and the second, the refined epoch of the Augustan age. The former produced only translators and imitators of Greek models; but it is probable that they succeeded better in tragedy than in comedy. Elevated expression usually appears rather stiff in a language not sufficiently cultivated, although it is attainable by perseverance; but to catch the negligent grace of social raillery, we must ourselves be possessed of humour and refinement. Here, however, as in the case of Plautus and Terence, we have not a single fragment of the Greek originals to enable us to judge of the accuracy and general felicity of the copies; but a speech of considerable length of the 'Freed Prometheus' of Attius is hardly unworthy of Æschylus, and is also, in versification, much more polished than the productions of the Latin comic writers generally are. This earlier style was carried to perfection by Pacuvius and Attius, whose pieces kept their place on the stage, and seem to have had many admirers down to the time of Cicero, and even later.

The contemporaries of Augustus were ambitious of measuring their powers with the Greeks in a more original way. The number of amateurs who attempted to shine in tragic composition was particularly great; and we find mention made even of works of the emperor himself. Hence there is strong reason for supposing that Horace wrote his epistle to the Pisos chiefly with a view to deter those young men from so dangerous a career, as they were probably infected by the prevalent literary passion without possessing the requisite talents. One of the most renowned tragic poets of that age was Asinius Pollio, a man of impassioned disposition, as Pliny informs us, and who, in plastic works, was fond of whatever bore the same character. It was he who brought with him from Rhodes the well-known group of the Farnesian Bull, and erected it at Rome. Ovid, who tried so many departments of poetry, likewise attempted tragedy, and was the author of a 'Medea;' and Quintilian asserts that he proved here, for once, what he could have done had he chosen to restrain himself, instead of yielding to his natural propensity to diffuseness.

These and all the other tragic attempts of the Augustan age have perished. Yet, according to all appearances, the loss to the interests of dramatic art is not very great. The Grecian tragedy had at first to struggle in Rome with all the inconveniences of a plant removed to a foreign soil: the Roman religion was in some degree related to the Greek, though by no means so completely the same as many have supposed; but the heroic mythology of the Greeks was merely introduced into Rome by the poets, and was in nowise connected with the national recollections.

From the sole specimen of the tragic talent of the Romans that remains to us it would, however, be unfair to draw a conclusion as to the productions of better times: we allude to the ten tragedies which go under the name of Seneca. [SENECA, in BIOG. DIV.]

With pagan Rome fell ancient dramatic art. Nevertheless there are one or two links of connection between the ancient drama and that of the middle ages, which modern writers have not always observed. There are even still existing some fragments of a play in Greek iambics on a Jewish Scripture subject, taken from the Exodus or departure of the Israelites from Egypt. The principal characters are "Moses, Sapphora, and God from the bush," that is, God speaking from the burning bush. Moses delivers the prologue in a speech of sixty lines, and his rod is turned into a serpent on the stage. The author of this piece, a Jew named Ezekiel, is supposed by Warton, the historian of English poetry, to have written it after the destruction of Jerusalem, to inspire his dispersed and captive brethren with hopes of deliverance under a new Moses, and to have composed it in imitation of the Greek drama, at the close of the 2nd century. (See the edition and German translation of L. M. Philipson, Berlin, 1830, 8vo.)

It appears that in the first ages of Christianity any one connected with the theatre was not allowed baptism. Among "the fathers," Cyril declares that when in our baptism we say "I renounce thee, Satan, and all thy works and pomps," those pomps of the devil are stage-plays and the like vanities. Tertullian, in like manner, affirms that they who in baptism renounce the devil and his pomps cannot go to a stage-play without turning apostates. Augustine, Cyprian, Basil, and Clement of Alexandria are no less vehement on the same point; and Chrysostom exclaims loudly against such as could listen to a comedian with the same ears with which they heard an evangelical preacher.

But when the blind zeal of the fathers against all heathen literature had been ironically seconded by the emperor Julian with an edict forbidding any Christian to be taught in the heathen schools or to make use of that learning, two ecclesiastics of that time, of considerable learning, undertook to supply in some degree the deficiency of instruction and entertainment experienced by their Christian brethren from the operation of Julian's law. These were Apollinarius, bishop of Laodicea, and his father, a priest of the same city. [APOLLINARIUS, in BIOG. DIV.] The latter not only, in treating Scriptural subjects, imitated on a large scale the great epic and lyric poets of Greece, but also turned various historical passages of the Old and New Testament into comedies and tragedies after the Greek model. Gregory Nazianzenus, archbishop of Constantinople, is said to have written plays; one only of those attributed to him is extant, a tragedy entitled 'Christ's Passion;' stated to be an imitation of Euripides, but made up, in fact, of scraps from that author. It is not known whether the religious dramas of the Apollinarii perished so early as some of their other writings, which were ordered to be destroyed for the very common offence of heresy; but certain it is that the species of literary culture which they endeavoured to supply gradually disappeared before the progress of Constantine's establishment.

In the general extinction of polite literature and liberal art, which darkened for so many centuries the moral face of Europe, every trace of truly dramatic performance or composition seems to have disappeared. The Saturnalian pageants—the Feast of Fools, the Feast of the Ass, &c.,—exhibited during that long interval, chiefly at the Christmas and New Year festivities, claim mention here, not as bearing much affinity to, but merely as in some degree filling up the place of, the old theatrical portion of the religious celebrations. To arrive once more at any indication of the general existence of what can with propriety be called a religious *drama*, we must descend to a later period of European history. And as in each of the great nations of modern Europe this religious drama gave way but gradually before that rise of the modern stage which accompanied the revival of letters, and has even, in one of those nations, strongly maintained its ground until very recent times, so as to become permanently incorporated, as it were, with the national theatre, we can most conveniently and effectively give such more particular notice of it in each nation as we have to present to our readers, in combination with the rapid view which we have to take of the rise and progress of the modern stage in each of the five great literary countries of Europe, namely, in Italy, Spain, France, Germany, and England.

Italian Drama.—After the long sleep of the true dramatic and theatrical spirit in the middle ages, which began to dawn again in mysteries and moralities independent of classical models, the first endeavour to imitate the ancients in their theatre, as in other departments of art and poetry, was made by the Italians. Nevertheless, apart from the religious plays, we find in the earliest dramatic attempts of modern Italy upon secular subjects a thorough independence of the classical rules. It is needless to follow through a series of now unknown names of persons who have written plays or translated them from the ancient classic authors. It will be sufficient to state that the Italians never had a national drama in the higher sense of the word. The comedies of Porta possess some merit, and the plays of Alfieri [ALFIERI, in BIOG. DIV.], composed upon a strictly classical model, are admirable and powerful works, but they have no pretence to nationality, though intended to promote a desire for freedom among his countrymen. The Italians, however, were fond of theatrical representations, and Trissino, Ariosto, Bibbiena, and Macchiavelli, all wrote comedies in imitation of the antique.

But something new was required; and Ottavio Rinnuccini invented the *melodrama*, which more commonly took the name of *opera per musica*, and which we now briefly term the opera. The magic power of this union of music with the romantic drama completed the triumph of the latter among the Italians of the 17th century; for not only was this musical melo-drama thenceforward their prime theatrical favourite, but the ordinary drama itself was no longer tolerated except under the romantic garb, and the Spanish school became for a time the model.

At the same time the public continued their favour to a species of comedy, or rather comic recitation, which in Italy seems to have been in all times peculiarly national. This was called the *commedia a soggetto* or *commedia dell' arte*. It consisted of the mere outline of a dramatic composition, wherein the parts very slightly sketched were assigned to the several performers, who were to fill them up extemporary. These sketches were called *scenari*, from their containing merely the argument of each scene: those of the comedian Flaminio Scala were particularly celebrated. Some of these *improvisatori*, especially those who appeared in the standing masks of Arlecchino, Pantalone, Puncinella, &c., displayed a liveliness of humour which, in spite of the great mass of empty buffoonery by which they were accompanied, made this kind of performance long continue to be well received by the Italians, until the more general cultivation given to the higher dramatic departments, and the general advance of social refinement, caused the improvisatory masks to be finally abandoned to the populace.

The task of classicising the musical drama was undertaken first by Apostolo Zeno, and afterwards, with more success, by the Abate Metastasio. [ZENI (*Apostolo Zeno*), and METASTASIO, in BIOG. DIV.] They were both of the French school, though Metastasio borrowed much of his intrigue from the Spanish dramatists, especially from Calderon; but failed to impart the spirit. Goldoni, about 1750, began to produce at Venice his comedies, formed generally on the French models [GOLDONI, in BIOG. DIV.], and displayed such abundant nature and fertility in painting the manners and the follies of his own age and country, that at length he brought the comedy of *character* into vogue, to the discredit both of the improvisatory farce and the melodrame. His first successes, however, received a severe check. The injury sustained by the masked and improvisatory comedy, for which the company of Sacchi in Venice had the highest talents, was one of the causes that led to the production, at this period, of the fantastic dramas of Gozzi. [GOZZI, COUNT CARLO, in BIOG. DIV.] These are fairy tales in a dramatic form, in which, however, along with the wonderful, versified, and serious part, this author introduced the whole of the masks, and allowed them the most unrestrained development, and the extravagant caricature of the Italian masks formed an admirable contrast to the wild wonders of the fairy tale.

In the latter period of the last century, Alfieri opened a new æra of Italian tragedy. [ALFIERI, in BIOG. DIV.] He adhered indeed to the established classic school, took his subjects chiefly from ancient story, and was a strict observer of the unities. Since his time MONTI and MANZONI are the only names that require to be mentioned among dramatic writers.

Spanish Drama.—In Spain, as elsewhere, it was the church that gave birth to the modern drama; but this remarkable circumstance is peculiar to Spain, that while in the other great nations of Europe the mature development of the drama detached it wholly from the service of religion, in the peninsula, on the contrary, the greatest dramatic geniuses constantly devoted a large portion of their efforts to religious compositions for ecclesiastical purposes; and the most perfect of all the Spanish theatrical poets made such compositions his favourite occupation. Owing to this very striking peculiarity of the Spanish stage, the source of which also will be indicated below, we defer some further notice of the spiritual plays of the Spaniards until we come to particularise the several species of their dramatic productions as exhibited in the most advanced period of their theatre.

The earliest performance that can strictly be called theatrical of which we find any mention in the Spanish annals, is that exhibited in 1414 at the coronation festival of Ferdinand the Good, king of Arragon. It was from the pen of the Marquis de Villena, a man who possessing intellectual acquirements prodigious for the time in which he lived, marched boldly, as a writer, in advance of his age and nation—so boldly, indeed, that all his writings were burned after his death, and this piece among them, so that its very title has perished. We only learn that it was an allegorical play, wherein figured the personages of Justice, Peace, Truth, and Clemency; so that it seems to have belonged to the class of *moralities* in vogue for a while in the infancy of the Spanish drama, and which Cervantes afterwards revived. Shortly after this attempt of Villena, his friend, the Marquis de Santillana, a man of equally extensive knowledge, and of equal freedom both of thought and pen, dramatised, under the title of 'Comediete de Ponza,' the incidents of a naval action which took place in 1435, near the island of Ponza, between the Genoese and the Arragonese, and in which the latter were defeated. This piece was never acted, nor was it printed among the author's works; its title, quoted in his letters, was all that was known of it until Sr. Martinez de la Rosa about thirty years ago discovered it among the manuscripts in the Royal Library of Paris. This interesting relic of the earliest efforts of the dramatic genius of Spain exhibits remarkable skill in the handling of an historical occurrence, as well as great beauty of plot, dialogue, and versification.

It was near the close of the 15th century that a sort of theatre was first established in Castile. The earliest dramatic attempt in this division of the peninsula was made by Juan de la Encina, who excelled in light poetry, and whose numerous works form a cancionero of themselves. After extending the field of religious representations by composing for exhibition on festival days a number of autos, wherein we find not mere paraphrases of Scripture, but conceptions of the poet's own, together with a certain dignity of action and language, he formed the project of carrying the stage beyond the walls of the church. With this view he composed some small pastoral pieces, which he denominated eclogues. These pieces, in which he himself enacted the principal parts, were first exhibited at the houses of the Admiral of Castile and the Duchess del Infantado. As their name indicates, they consisted of nothing more than a dialogue between two or more shepherds. The author, imitating Virgil, used this expedient in the first instance to celebrate, by means of allusion, some particular event, such as the conclusion of a peace, or the return of a prince: and next, he invented some short and simple action wherein he brought into play the passions of his interlocutors themselves. These little pieces, interrupted by dances and ending with songs (villancicos) usually contained also some farcical scenes; so that they may be said to have comprised at once the elements of the comedy, the ballet, and the vaudeville; and they have in them much grace and wit, as well as nature and liveliness. The first performance of these pastoral comedies took place in the year 1492, so memorable in the Spanish annals as being that of the conquest of Granada and the discovery of the New World.

About the same time appeared the famous 'Celestina,' begun by Rodrigo Cota and finished by Fernando Rójas de Montalvin. Though entitled a "tragi-comedy," it was never performed, nor was it capable of being so, as it was in reality but a tale told in dialogue. Yet the singular merit of this truly primitive composition, which went through several editions, and was translated into almost every European language, contributed much to the advancement of the stage by furnishing a genuine model of dramatic diction.

It was in the beginning of the 16th century that to these various attempts succeeded the first regular Spanish dramas, but, through a singular concurrence of circumstances, they appeared out of Spain. Bartolome de Torres-Naharro, long a captive in the hands of the Moors, and residing at Rome after his redemption, there composed some comedies in his native language, and got them performed at the tasteful and voluptuous court of Leo X. In the compositions of Torres-Naharro, though little known, and unjustly depreciated by Signorelli in his 'Historia Critica del Teatri,' there is much happiness of invention, well-drawn character, and spirited dialogue; they have also the licentious tone of the Italian comedies of that period, and contain some strokes of a malicious boldness peculiar to the author, who, though a priest, and living at the pontifical court, composed satires against the church such as Luther himself might have dictated. He also invented the introïto, or prologue, and gave to the acts the name which they have ever since borne, of jornadas, that is, journeys or stages, alluding to the pauses or resting-places for the actor and the spectator.

No sooner did Naharro's pieces find their way to Spain (about 1520) than they were proscribed by the Inquisition, so watchful to extirpate every trace of Protestantism. The like sentence fell upon those written shortly after in Germany by the author of the 'Satire on Women,' Cristoval de Castillejo, secretary to the emperors Maximilian and Ferdinand. These latter pieces, which it was not deemed prudent to publish among the author's works when the prohibition was taken off in 1573, but which are known to have been of the satirical and licentious class, are entirely lost. So that the Spanish stage presents the singular phenomenon of having really had two infancies. The first attempts in regular dramatic composition being suppressed by the formidable authority above-mentioned, found no imitators, and even seem to have been completely forgotten, for it was a play of Ariosto's that was exhibited at the marriage of an infanta in 1548. Some few classical scholars, indeed, as Villalobos, Fernan Perez de Oliva, and Simon de Abril, strove to bring forward the ancients as dramatic models, by translating Plautus, Terence, and Aristophanes; but their works were still less adapted to take possession of the national mind. So that while, of those dramatic productions which Spain already possessed, one part lay hidden in the libraries of a few of the learned, and the other buried in the archives of the Inquisition, the people were abandoned to the gross merriment of the jugglers and buffoons. Hence it is that Schlegel, Bouterwek, Sismondi, and almost every other foreign critic, apparently ignorant even of the names of the first dramatic writers of Spain, make no mention of them, but fix the middle of the 16th century as the period of the earliest origin of the Spanish drama.

The founder of the truly national and popular theatre of Spain was Lope de Rueda, of Seville, who quitted his trade of a goldbeater to join a company of strollers, of whom he shortly became the chief, or, according to the Spanish expression, the *autor*. This title, derived, not from the Latin *auctor*, but from *auto*, an act or performance, was at that time given to one who composed and recited pieces, and is still retained to signify the manager of a company of comedians. Lope de Rueda united the two kinds of talent necessary to an *autor* of that period; had prodigious success; was unanimously declared to be both a great poet and a great performer; and the grandees of the time crowded to the diversion which his exhibitions afforded them from the gloomy gravity of the palace of Philip II. The few of his plays, pastoral dialogues, &c., that remain, are distinguished for natural grace and liveliness; and though these are all in prose, he wrote with equal facility in verse.

"In the time of this celebrated Spanish actor," says Cervantes in the preface to his own published plays, "the whole wardrobe of an *autor* could be thrust into a bag: there were three or four close vests of white skin trimmed with gilt leather, and the like number of beards, wigs, and trunk hose. The plays were colloquies in the manner of eclogues, between two or three shepherds and some shepherdess, and were eked out with two or three interludes (*entremeses*) exhibiting sometimes the character of a negress, sometimes of a bravo, sometimes of a simpleton, sometimes of a Biscayan; for these characters and many others Lope represented with the greatest truth and perfection imaginable. At that time there were neither machinery, nor decorations, nor combats between Moor and Christian, on foot or on horseback: there were no figures made to issue through the boards of the stage as from the centre of the earth; still less were any angels or souls let down from heaven upon clouds. The stage consisted of four planks, laid in a square form across four benches, which raised them four hands from the ground. The whole decoration consisted of an old coverlet, which was drawn from one end to the other by two cords, to make what was called the *vestiario*, or dressing-room, and behind which were the musicians, who sang, without the guitar, some ancient *romance*."

Shortly after, Juan de Malara, a celebrated professor of the *humanities*, caused a versified drama of his, entitled 'Locusta,' which he had written at first in Latin, to be acted at Salamanca. Then came an actor of Toledo, named Navarro, who, Cervantes tells us, converted the manager's clothes'-bag into the more important-looking form of trunks and portmanteaus; brought forth the music from behind the hanging; took the false beards from the chins of those whose parts did not require them; invented machinery, clouds, thunder and lightning, duels and battles. Moral development, too, accompanied this material progress: the pieces now began to display something like a plot, and some of the animation which arises from conflicting interests and passions. The titles of a few of these may afford some notion of this transitional, or, more properly, adolescent period of the Spanish theatre: there were, for instance, 'Dido and Æneas, or the Pious Trojan,' 'The Grand Prior of Castile,' 'Loyalty against One's King,' 'The Sun at Midnight and the Stars at Noon,' 'The Taking of Seville by St. Ferdinand,' and 'The Cortes of Death;' the costume of which latter piece is so humorously described in a passage of the second part of Don Quixote.

About 1580 were established at Madrid the two theatres *de la Cruz* and *del Principe*, which are still existing; and now some superior minds turned their efforts to dramatic composition, which had hitherto been left entirely to the managers of strolling companies. Cervantes, just returned from his eventful Algerine captivity, was one of the earliest adventurers in this career. "I was the first," he tells us, "that exhibited the imaginings and hidden thoughts of the soul, by bringing forward moral characters on the stage, which I did with warm and general applause from the public. I wrote at that period some twenty or thirty plays, which were all acted unsaluted by cucumbers or any other matters convenient for pelting with; they ran their course free from hissing, shouting, or clamour." Cervantes, indeed, advanced the Spanish drama most importantly, both as to dramatic invention and moral dignity. His 'Numancia,' in particular, one of the only two of these his earlier dramatic productions that have found their way to the press, is very remarkable in the dramatic history of Europe. [Saavedra, in Biog. Div.]

Cervantes wrote at Madrid; and at the same time Juan de la Cueva produced some dramas on the stage of Seville, reducing to four the number of jornadas, or acts, which had hitherto been five or six. The day's performance then consisted, besides the principal piece, of three *entremeses*, or interludes, played between the acts, and a little ballet. Valencia, too, which had always, in arts and letters, its rival school to that of Seville, made some advances in the dramatic career. It was a Valencian poet, Cristobal de Virues, who further reduced the number of acts from four to three, which latter number was thenceforward adhered to by all Spanish writers. "Until then," according to the ludicrous conceit of Lope de Vega, "the Spanish drama had *gone on all fours*, like a child, because it was yet in its infancy."

The scenic pomp of the Spanish theatre had already made great progress. The same writer, Rojas, who said that in the days of Lope de Rueda an *autor* and his company might have deposited their bundle of *properties* upon a spider's back, relates that in the time of Cueva and Virues, women played their parts in dresses of silk and velvet, with chains of gold and pearls; that, in the interludes, airs were executed by three or four voices; and that even horses were introduced in the warlike plays to complete the illusion.

It is well worthy of remark that already, in the 16th century, we find in Spain the contest fully and warmly engaged between the claims of the dramatic writers to an absolute independence of the classic rules, and the critics demanding a rigid adherence to the precepts of Aristotle. Thus while the rhetorician Pinciano was zealously conjuring the theatrical writers to respect the unities, for which they showed little regard, one of them, Juan de la Cueva, openly undertook, in his 'Exemplar Poetico,' the defence of the dramatic liberties. He claimed them as the offspring of that succession of ages which had abolished all antique laws,—as more favourable to the boldest flights of imagination,—and in fine, as better adapted to please the public. But, while delivering this judicious opinion, he lays down such maxims for the regulation of this dramatic freedom as good sense and good taste must ever dictate, though his countrymen, in their fiery impatience of any such restriction, have not paid them sufficient attention.

The Spaniards had conquered the Moors, they had subdued South America, but they had lost the more important part of their liberties, and they had become the willing slaves of their church. They had glorious recollections, with an indomitable personal pride, and they still retained a varnish of their old manners and feelings. It has been well observed by Mr. H. Chorley, in some ingenious papers on the Spanish drama in 'Fraser's Magazine,' for 1859, that there is no understanding the Spanish drama after the time of Lope de Vega, without a thorough understanding of the national character. The English reader who meets with heroes who lie, seduce their friends, wives or sisters, and murder those who even seek interviews with their own; who possess few or no estimable qualities, but a frantic bravery and readiness by fighting to wash out in the blood of their adversary any spot on their honour that has been brought to light, cannot but consider them as unnatural, unless they recollect that these crimes were held to be venial if accompanied by an unswerving faith in the power of the church to pardon them, and a belief in the might of a miraculous interposition of their adopted saints.

The Spanish drama attained its greatest excellence about the same time that it flourished in England; and by some an affinity has been claimed. There is, in fact, but little resemblance except in the freedom of both from the conventional classical rules. A most essential difference is pointed out by Mr. G. H. Lewes, in his 'Spanish Drama' (Knight's 'Weekly Volumes,' 1846), in the one being an evolution of plot, the other an evolution of character and passion; that the one, so far resembling the drama of other southern nations, is *objective*, the other, like most of the northern nations, *subjective*. He says, "Calderon and Shakspere are the opposite poles of intellectual action. The tendency of the Spaniard is to transform all thoughts into sensations; that of the Englishman to transform all sensations into thoughts." The Spanish drama depicts personifications or actions, but developes none of the subtler traits of character. The Spanish people admired a devoted loyalty to their monarch, a blind faith in their religion, and unquailing courage. These constituted a hero. In a somewhat milder form these requisites were also necessary to their heroines.

Such was the public mind upon which Lope de Vega arose to exercise his marvellous fertility of dramatic invention and facility of metrical composition. He had the first great requisite for success in this career, a most thorough knowledge of the tastes and passions of the people for whom he wrote; but that further and nobler merit, an elevated view of his art and deep devotion to it for its own sake, he never evinced. [Vega, Lope de, in Biog. Div.] Contemporary, or nearly so, with Vega, there were many imitators of him, but none who approached him in excellence. But near the close of his life arose Calderon de la Burca [Biog. Div.], who was destined to supersede him, or nearly so, in the estimation of his countrymen. To him succeeded Moreto, who, with less of the national fire, paid somewhat more attention to the development of character in his plays; and Gabriel Tellez, who wrote under the assumed name of Tirso de Molina, whose plays are chiefly remarkable for their want of gaiety, and a frequent disregard of probability. [Tellez, in Biog. Div.]

It is remarkable that during this, the most brilliant period of the Spanish stage, the council of Castile ventured to propose, as a condition of the re-opening of the theatres, which, on account of court mournings, had remained shut from 1644 to 1649, that the plays to be performed should be confined to subjects of good example taken from edifying lives and deaths, without any mixture of love; that consequently, nearly all those which had theretofore been acted should be prohibited, especially the works of Lope de Vega, which had been so prejudicial to good morals. But fortunately, the taste of the monarch, in accordance with that of the public, made him reject the proposal of his austere advisers.

The patronage of the monarch, the court, and the nation, had thrown a multitude of literary men into that career, then the most honoured and the most lucrative. Thus, besides Moreto, who has been considered as one of the models of Molière, there were a host of dramatists of the second order, at the head of whom must be ranked Francisco de Rojas, who had all the qualifications of Moreto, but exceeded him in his defects. Then follow Guillen de Castro, Ruis de Alarcon, La Hoz, Diamante, Mendoza, Belmonte, the brothers Figueroas (who wrote conjointly, like the French vaudevillists of the present day), Cancer, Enciso, Salazar, and Bances Candamo, each of whom, though establishing no school, produced at least some important composition.

The disasters that befel the Spanish monarchy in the latter years of the reign of Philip IV., together with a succession of court mournings which closed the theatres for a considerable time, gave the first blow to the dramatic art in Spain. In 1665, the death of that prince, who had been its most zealous protector, gave the signal for its rapid and through decline. His successor, the imbecile Charles II., was yet in his infancy; and the queen-regent signalised the commencement of her administration by a decree, dictated no doubt by her spiritual director, the jesuit Nitard, and certainly unique in dramatic history; she commanded "that all plays do cease until the king my son shall be old enough to be entertained by them." Although this strange order could not be rigorously executed, yet the decay was so great that, in 1679, at the marriage of Charles II. with a niece of Louis XIV., wherein all possible magnificence was displayed, no more than three companies could be got together to perform at court.

During this period one writer alone endeavoured to support the tottering stage; Solis, the eloquent historian of the conquest of Mexico, likewise devoted to the service of the theatre his brilliant imagination, polished wit, and glowing style. He has left us several plays well worthy of the dramatic period which he survived, one of which especially, entitled 'Love à la Mode' (El Amor al Uso), has peculiar excellence.

With Solis may be said to have expired the Spanish theatre properly so called. The elevation of Philip V. to the throne of Spain having given prevalence to the French taste, and introduced, at court at least, the habits and manners of the court of Louis XIV., the Spaniards, after having been the dramatic precursors and teachers of the French, were content to become their humble translators and copyists. In the course of the 18th century, it is true, some attempts to re-erect a national drama were made successively by Zamora, Luzan, Canizares, and Jovellanos; but these honourable endeavours had but a transitory success; and to arrive at a work of originality—after, however, noticing as such the *sainetes* (small satirical pieces) of Ramon de la Cruz—we must come down to the commencement of the present century, to Moratin, the witty and elegant author of 'The Coffee-house,' 'The Baron,' 'The Maiden's Yes,' &c., and next, to Martinez de la Rosa, who wrote 'The Mother at the Ball and the Daughter at Home.'

The few specimens of the Spanish drama in the classic style, consist chiefly of translations from, or adaptations of, plays from the Greek, the Italian, or the French; and although occasionally a mixture of the romantic was introduced, they never became popular, and are not worth enumerating.

Although the performance of the *autos sacramentales* on the ordinary stage was suppressed in 1765, in the reign of Charles III., yet the seasons of Advent and Lent, and more especially the Holy Week, are still solemnised by the like representations in the great churches; a sort of stage, called *the monument*, is erected in the choir, upon which are played the acts of the Passion, wherein the numerous characters that successively figure in the piece still wear the costume of the middle ages as it must have been at the origin of these exhibitions,—san-benitos, black masks, high pointed caps, long skirts, belts, or rather breastplates, made of cords,—all the wardrobe, in short, of an *auto-da-fe* procession.

French Drama.—In France the *mysteries* appear to have had their immediate source in the pilgrimages so common in those days. Menestrier tells us ('Représentations en Musique Anciennes et Modernes') that the pilgrims to the Holy Land, St. James of Galicia, Mont St. Michel in Normandy, and the various other places of pious resort in France and abroad, used to compose rude songs on their travels, wherein they introduced a recital of the life and death of Christ, or of the last judgment: in others they celebrated the miracles of saints, their martyrdom, and divers wonderful visions and apparitions. These pilgrims, going in companies, and taking their stand in the streets and public places, where they sang with their staves in their hands, and their hats and mantles covered with shells, and painted images of various colours, formed a kind of spectacle which pleased the public of that day, and at Paris excited the piety of some of the citizens to raise a fund for purchasing a proper place in which to erect a stage whereon these performances might be regularly exhibited on holidays, as well for the instruction of the people as for their entertainment. This appears to have been the origin of the society at Paris called the Brethren of the Passion. In 1402 Charles VI. authorised these exhibitions by letters patent; the Premonstratensian monks gave the use of a great hall of their convent, and a stage was constructed in it upon which the fraternity enacted scriptural pieces. The ecclesiastics crowded to these exhibitions; stages soon arose in every province; and the *mystères* were so much relished, that on holidays the hour of vespers was hastened, that the people might have more ample time to be present at the play. The brethren, to vary the attractions of the performance, added a sort of farcical interludes or after-pieces of a merely worldly character, the enacting of which however, careful of their own histrionic dignity, they delegated to a junior society called that of the *Enfans sans Soucis*. These latter pieces, in allusion to their burlesque and buffoon character, were denominated *sottises* or *soties*.

The stage upon which the mysteries were played consisted of several scaffoldings one above another: the most elevated of all represented heaven; that immediately beneath it, earth; a third, still lower, the palace of Herod, the house of Pilate, &c.; and hell, which was at the bottom and in front, was figured by the gaping mouth of a dragon, which opened and shut as the devils went in and out. On each side were seats rising in steps one above another, on which the actors rested when they were not upon the stage, a contrivance not very favourable to scenic illusion; and at the back was a recess, with curtains drawn across it, for the exhibition of such matters as were supposed to take place in the interior of a house.

Among the French, as elsewhere, the Passion was the primary, the most constant, and most solemn subject of these representations; the parts of Christ on the cross, Judas hanging himself, &c., being all played by real persons, sometimes at the actual peril of their lives. It seems to have been owing chiefly to the efforts of the early reformers to diffuse a knowledge of the Scriptures among the people that the Romish ecclesiastics throughout Europe, as one means of securing the fidelity of their flocks, proceeded studiously to extend the field of the religious representations so as to embrace the whole series of Old and New Testament history, or as much of that history as they deemed it prudent to disclose to the multitude. This zealous exertion on the part of the Catholic clergy was supported by all the authority of the Catholic princes. Thus we find that in 1541, under Francis I., the performance of a grand mystery of the Acts of the Apostles was proclaimed with great solemnity under the royal authority, and acted at Paris in the course of many successive days, before the nobility, clergy, and a great concourse of people, in the Hôtel de Flandres. These plays, written in French rhyme by the brothers Greban, were printed in 2 vols. folio, black letter, under patent of the king to one Guillaume Alabat, of Bourges. The dramatis personæ are, God the Father, the Son, and the Holy Ghost; the Virgin and Joseph; archangels, angels, apostles, and disciples; Jewish priests, emperors, philosophers, magicians, Lucifer, Satan, Beelzebub, Belial, Cerberus, and a multitude of other celestial, terrestrial, and infernal personages, amounting altogether to nearly five hundred. The subjects of these plays are chiefly scriptural; but many of them are from apocryphal New Testament subjects, and the whole forms a strange medley of sacred and profane history. This grand performance was executed, not by any standing company, but by actors selected from the people at large after trial of the merits of the respective candidates.

Among the numerous legendary pieces, one of the most curious extant is 'The Mystery of the Knight who gives his Wife to the Devil' (Le Mystère du Chevalier qui donne sa Femme au Diable); but the most universally popular of them all seems to have been that of the miraculous host, or consecrated wafer, tortured by a Jew at Paris, commonly called 'Le Mystère de la Sainte Hostie,' two several versions of which exist in black letter.

After the *mystères* and the *soties*, and during their continuance, came the *moralités* and the *farces*, of which the clerks of the Basoche were the inventors. These clerks were the young assistants of the procureurs, or solicitors, to whom Philippe le Bel granted the privilege of choosing from among themselves a chief, to be called their king, to have supreme jurisdiction over their body, and even to coin money for currency among the clerks. Francis I., in requital of the service rendered him by the king of the Basoche and 6000 of his clerks in marching against the revolters of Guienne, presented them, in 1547, with an extensive promenade ground, bordering on the Seine, which thence took the name of *Pré aux Clercs*. As early as the commencement of the 15th century, the king of the Basoche used every year, in July, to make a review of his clerks, divided into twelve bands under as many commanders. After the review they went and offered their salutations to those gentlemen at the head of the legal profession who composed the parliament of Paris; and then they went and performed a morality or a farce. The brethren of the Passion having the exclusive privilege of acting mysteries, the clerks were driven to the invention of the moralities, which were purely allegorical pieces personifying the vices and virtues. The farces and the soties, on the other hand, took a satirical turn, the success of which soon carried the authors to licentious extremes. The public calamities and violent political dissensions of the reigns of Charles VI. and Charles VII. favoured this tendency: the two leading parties, the Armagnacs and the Burgundians, had each its poet, and insulted each other by turns upon the stage. When public order was restored, the royal authority availed itself of the fair pretext which these satirical excesses afforded to suppress this exclusively popular stage altogether: the clerks were forbidden to play either farce, sotie, or morality, on pain of flagellation and banishment. This suspension continued until the reign of a prince who was less afraid to hear the truth.

The society of the *Enfans sans Soucis*, too, already mentioned, had been established under Charles VI., had been authorised by patent, and had suffered political oppression. Louis XII. took them likewise under his protection; and their most celebrated sotie, entitled 'The Abuse of the World' (L'Abus du Monde) is attributed to the historian Bouchet above quoted. Their farces have been more celebrated, especially that of 'Pathelin,' whose name has ever since been proverbial in France. The dialogue itself, written in octosyllabic rhyme, is full of humour; and from one passage it may be mentioned that Lafontaine has taken his charming fable, 'Le Renard et le Corbeau.' This piece, with all its levity, is very interesting, as one of the most truly original and national productions of the early French stage, and therefore as one of those which gave promise of something like that spontaneous and vigorous dramatic growth which was springing up in one or two neighbouring countries. But the three several kinds of theatre which we have particularised were fated soon to sink under the repeated blows aimed at them by the government. To this determined stifling by the government of the first germs of a truly national drama we ought to attribute the immediate and general success of the earliest French imitations of the ancient theatre that were actually brought upon the stage. The national taste—the *romantic* tendencies of which had decidedly manifested themselves—was not suffered to develop itself freely. Theatrical enjoyment, since they first tasted it, has ever appeared a more imperious *want* of the French, and of the Parisians in particular, than of any other people, excepting perhaps the ancient Athenians; and when, at the period in question, their rulers had violently crushed every other species of dramatic production, they eagerly welcomed those only forms of it which those rulers would vouchsafe to let them have.

Some French translations from Sophocles and Euripides already existed, but nobody had yet thought of adapting them to the stage; indeed they were little to the purpose either of the brethren of the Passion or the performers of the Basoche. A young gentleman, Etienne Jodelle, seigneur of Limodin, who had studied the ancient dramatists both in their original works and in the Italian imitations of them, was the first to avail himself of the opportunity thus afforded, by bringing forward his 'Cléopatre Captive,' a tragedy in five acts, with choruses after the manner of the Greeks. His friends got a stage erected in the Hôtel de Reims at Paris; two poets of note in that day, Remi Belleau and Jean de la Péruse, undertook the principal male parts; and Jodelle himself, trusting to his youth, his personal beauty, and histrionic talent, personated Cleopatra. This piece is remarkable only as being the first of its class, and so commencing a new era of French dramatic history. Jodelle was more successful in his comedy entitled 'L'Abbé Eugène,' in which there is much comic power and sprightliness.

From Jodelle down to Corneille, French dramatic art made little progress; but dramatic productions, in the same line of classic imitation, abounded, especially in tragedy, the heroes of which were constantly taken from Greek or Roman history, or at most from that of the Turks, who were first introduced upon the stage by Gabriel Bonnin. At this early period, indeed, of the French theatre, that singular dramatic prejudice seems to have firmly established itself, that the pomp of tragic style could not be well supported on the stage, except both costume and character were either Greek, Roman, or Mussulman. The Alexandrine verse, too, was almost invariably used; though once, and but once, was acted a prose tragedy of 'Sophonisba,' by St. Gelais. The versified comedies of the same period have nothing remarkable; but in 1562 the two brothers De la Taille began to accustom the French public to comedies in prose. Nicolas Filleul attempted unsuccessfully to naturalise pastoral poetry on the stage. All these writers had still to contend against the privileged possessors of the stage. There was not in all France a single company regularly trained for the new class of performances. Under Henry IV., the brethren of the Passion had obtained almost a revocation of the edict of 1548, which prohibited them from enacting religious subjects; but the public had now little relish for these rude exhibitions, so that the fraternity found themselves obliged to let their theatre to a more modern class of performers. The other dramatic societies endeavoured to adapt their antiquated pieces in some degree to the modern taste; and thus out of their old moralities they contrived to make pastoral pieces wherein the Church was a bride, and Christ the bridegroom. Robert Garnier rose in tragedy some little above his predecessors in elegance and dignity, and was so much celebrated in his own day as to have the pre-eminence of his tragic powers commemorated in one of the best sonnets of Ronsard. Though he usually drew abundantly from Sophocles, Euripides, and Seneca, he showed in some of his pieces more original vigour, as, for instance, in 'Les Juives,' taken from Jewish history. The prose comedy of intrigue (for the comedy of character had not yet appeared) continued to be cultivated with vigour and success by Pierre de l'Arivey, contemporary with Garnier. The Jesuit father Fronton attempted a tragedy on the grand national subject of 'Jeanne d'Arc,' but without success. At length, in 1600, two permanent theatres were erected at Paris, one of which was occupied by a company which took the title of *Troupe de la Comédie Française;* the other company established itself in the quarter of Paris called the Marais, with the consent of the brethren of the Passion, and thus the old stage of the middle ages was finally extinguished in the French metropolis. Still, however, as before, the theatre took its tone from the exclusive taste of the court; and from the commencement of the 16th century till the appearance of Corneille, scarcely anything was brought forward but either tragedy or that very harmless description of farce which, it was thought, might without much danger be conceded to the popular taste. This is the grand era of the popularity of the well-known burlesque personages *Gros Guillaume, Tabarin,* and *Turlupin,* whose merry reign was protracted even into the age of Louis XIV.

Most of the tragedies of this period flowed from the exhaustless pen of Alexandre Hardy, a poet employed by the company which had succeeded to the privilege of the brethren of the Passion, and who wrote more than eight hundred dramatic pieces, of which forty remain. Possessed of very extensive reading, Hardy made some efforts to deviate from the beaten track of his predecessors: he ventured in some instances to compose what he called tragi-comedies, one of which is founded on a tale of Cervantes; but his genius was not equal to his boldness and facility. The dramatists who immediately preceded Corneille and Molière were Mairet and Tristan, the former of whom, like so many before and after him, tried and failed in the eternal subject of Sophonisba; while the latter failed yet more signally in the Jewish subject of Mariamne.

We now come to the age of Louis XIV., of which Cardinal Richelieu was the real creator in literature, as well as in politics. This great artificer of despotism had the sagacity to perceive that, in order to consolidate his favourite political fabric the more, it was worth while to permanently organise the literary talent of the country in the service of the court. The court, it is true, did not directly dictate to the cardinal's chosen forty in what quarters they should bestow their praise or censure; but things were so ordered that the men to whom the protectorship of letters was officially entrusted should always share more or less the tastes and opinions of the government: by the court it was that they were paid; under the eyes of the court they held their sittings; it was by court intrigue that a vacant chair was to be obtained, and every writer was ambitious of that honour.

Such was the predominant influence under which Corneille began his dramatic career. To enter the academy, he must please the court; and to please the court, he must defer to the literary dictation of the academy. Now, in dramatic composition, the academy not merely recommended adherence to the so-called rules of Aristotle, but prescribed their observance with the greatest rigidity. The tragedy of France became conventional; the structure of the verse, and the opportunities it gave for a studied and correct declamation of passages of poetical beauty and of lofty sentiments, gained the popular ear; and the subtle delineation of character, except in the marked features of love, ambition, or revenge, were neglected, or only displayed in occasional passages by the men of real genius, who, reflecting the feelings of their age, composed their dramas to suit the national taste. Some little romance was introduced from the Spanish school, but curtailed to tameness to fit the Procrustean bed they had chosen. Their productions have been treated of under the heads of CORNEILLE, RACINE, VOLTAIRE, &c., in the BIOG. DIV.

The rise of the French comedy of character, of which Molière is the great representative, is yet more clearly connected with the Spanish source than that of their classic tragedy. But Molière was born for the comic only, and could indulge his dramatic tastes and propensities with comparatively little restraint. In his first pieces, written for a strolling company, he imitated the lively trickery and buffoonery of the Italian farces, a species of composition for which, throughout his career, he showed a strong inclination. [MOLIÈRE, in BIOG. DIV.]

The restrictions which cramped the genius of Corneille comfortably fitted that of Racine, and contributed to render him in every sense the favourite tragic poet of the court of Louis XIV. He seemed born to carry to the highest possible perfection what we must call, for want of a neater term that should be equally appropriate, the Frenchification of Greek tragedy. [RACINE, in BIOG. DIV.]

In the history of French tragedy, it is little gratifying to pass from Racine to Richelieu's favourite, the Abbé D'Aubignac, who revenged himself for the failure of his tragedy of 'Zénobie' by censuring bitterly the works of Corneille. Racine himself found a similar adversary in Nicholas Pradon, who wrote a rival tragedy of 'Phèdre,' which Madame Deshoulières was not ashamed to extol above Racine's, and a 'Régulus,' which the praises of St. Evremond and Madame de Sévigné have not saved from oblivion. Lafosse profited somewhat better by Corneille's example in the dignity and intelligence which he threw into his otherwise feeble 'Manlius.' As for the tragedies of Duché, Campistron, the abbé Pellegrin, the abbé Longepierre, and others, suffice it to say, that they brought little fame to their authors, and no advancement to the art. Thomas Corneille ventured to write tragedy after his brother, and wrote it very "correctly." Crébillon was by far the most successful tragic writer that arose in the interval between Racine and Voltaire; but his reputation was rapidly acquired. [CORNEILLE, THOS., in BIOG. DIV.]

This species of composition occupied no small proportion of the wonderful versatility of Voltaire, who has earned, in universal estimation, a place beside Corneille and Racine as a dramatic artist. [VOLTAIRE, in BIOG. DIV.]

La Harpe, whose critical labours had so extensively injurious an influence throughout Europe in enforcing the classic system in all its rigidity, contributed nothing to recommend it by his own tragic compositions, which, while they are among the most correct in style, are among the most frigid in sentiment and effect. On the other hand, Marie Joseph Chénier, who, flourishing in the early days of the Revolution, wrote, like the tragic poets of Greece, in the midst of free men, and with like ardour stimulated them to the love of liberty, made nearer approaches than any of his predecessors to the tragic strength and fervid diction of Voltaire. His 'Charles the Ninth, or the School for Kings' (École des Rois), was that among his pieces which produced the greatest excitement in the public mind. Ducis, possessing brilliant powers of poetic execution, in his tragedy of 'Albufar' pictured his ideas of Arabian manners with great warmth of imagination and originality of style: but his highest claim to dramatic celebrity rests upon the endeavour which he made to bring his countrymen acquainted with the masterpieces of Shakespere. The name of M. Arnault appears already in the dramatic annals of that period. His first tragedies, 'Marius à Minturnes,' 'Lucrece,' and 'Cincinnatus,' with their energetic simplicity, are in spirit and design a copy of the antique. Gabriel Legouvé's 'Death of Abel' (Mort d'Abel) was a hazardous but successful attempt to make an antediluvian subject acceptable on a modern stage, to which he had been encouraged by the popularity which Gessne, and his poetry then enjoyed. The same author ventured to exhibit, not unsuccessfully, in 'Epicharis et Néron,' the latter days of Nero, the opening of whose career is shown in one of the masterpieces of Racine. 'Les Templiers' of M. Raynouard, founded on the destruction of the order of Knights Templars in the reign of Philippe le Bel, is much more remarkable for art and correctness of structure and execution than for poetic vitality; but these merits, added to the powerful interest of its national subject, made it highly successful.

Some of the comedies of Boursault, a younger contemporary of Molière, have kept possession of the stage: they are all of the secondary description which the French call *pièces à tiroir*, of which Molière himself, in his 'Fâcheux,' gave the first example. This kind, in the accidental nature of the scenes, which are strung together on one common occasion, bear a resemblance to the *mimi* of the ancients: they are particularly favourable for the display of the mimetic art in the more limited signification of the term, as it is one and the same player that re-appears throughout in a fresh character and a different disguise. The want of dramatic movement however in such productions requires they should be short, whereas Boursault's pieces, though otherwise possessing considerable merit, are drawn out to the wearisome length of five acts.

After Molière's death, a considerable time elapsed before the appearance of Regnard, to whom the second place among the French comic writers has usually been assigned. [REGNARD, in BIOG. DIV.]

The 18th century produced a number of comic writers in France of the second and third rank, but no genius capable of advancing that department of the dramatic art a step farther, and thus the belief in the unapproachable excellence of Molière, became yet more firmly fixed.

In the overthrow of the *ancien régime* in politics fell the main support of the old dramatic code; yet it is remarkable, though perhaps not wonderful, that many of the warmest and firmest opponents of the former rule, both then and since, have clung to the classical literary canons; so strong and so binding is the force of habit, especially of literary habit, so long as the analytic powers have not been brought to bear directly and expressly upon the subject in question. The revolution in French art and literature consequently followed but tardily the political revolution; and its first promoters had to contend against the most formidable obstacles. However, they presented themselves early in the field. The stormy days of the Convention, and the saturnalian period of the Directory which followed, did indeed afford little leisure or encouragement for the cultivation of the liberal arts; but no sooner were the danger and the fear of anarchy removed by the firm and vigorous administration of the Consulate, than the new literary and dramatic ideas began to develope themselves, and, in consequence, a violent war to be waged between the *classicistes* of the old school and the *romanticistes* of the new.

Among the earliest, ablest, and steadiest cultivators of the French romantic drama, the first place seems due to M. Népomucène Lemercier. His tragedy of 'Agamemnon' combines felicity of plot, purity of style, and discrimination in depicting characters and manners.

The revolution of 1830 was a victory won for liberty in art as well as in politics. Since then, the higher departments of the French drama, both as to writing and acting, have been in full activity. Among the advocates and emulators of the Shaksperian *drama*, Victor Hugo has hitherto shown himself the foremost, the boldest, and the ablest. In tragedy in the more limited sense, though still of the romantic school, Alexandre Dumas and Alfred de Vigny are the most distinguished. It is the higher comedy that seems at present to be the least flourishing. Meanwhile, the classic reputation of Molière preserves his comedies on the stage, although in tone and manners they are altogether obsolete. But we do not intend to enter upon disquisitions of the merits of contemporaneous writers; we may, however, state that they have been very successful in the minor departments of the dramatic art; and that numerous farces and interludes have a high degree of wit, satire, and ornamental characterisation.

The serious or ideal French opera dates from the time of Louis XIV. Cardinal Mazarin, himself an Italian, had introduced into France the taste for the Italian opera. Louis too was desirous of rivalling or surpassing foreign nations in the external magnificence of the drama—in decoration, machinery, music, and dancing; these were to be used on festival occasions at court, and accordingly Molière was employed to write gay operas, and Quinault grave ones, for the music of Lulli. As Quinault is the only great poetical name in the history of the higher French opera, we refer to the notice of him [QUINAULT, in BIOG. DIV.] for further remarks on that particular species. The *operette*, or comic opera, has been much more successfully cultivated by modern French writers, owing, in a great degree, to the substitution, in this kind, of ordinary dialogue in lieu of recitative, so unfavourable to dramatic animation. The *vaudeville*, in which the lighter dramatic writers of France have of late been so wonderfully prolific, and which so peculiarly harmonises with the tone of good-natured gaiety in the more popular classes of that country, is but a variety of the comic opera; its essential distinction being, that it dispenses with musical composition, as the songs are set to well-known popular airs.

It is a fact worthy of attention, that the histrionic art, especially in tragedy and the higher comedy, has long been carried in France to very high perfection. Schlegel himself admits, that in external dignity, quickness, correctness of memory, and in a wonderful degree of propriety and elegance in the delivery of verse, the best French actors can hardly be surpassed.

German Drama.—The earliest mention of the performance of Mysteries in Germany appears in the 'Eulen-spiegel,' which professes to be the history of a celebrated buffoon of that name, who is stated to have lived about the middle of the 14th century, although the book itself is not older than the beginning of the 15th. We there find, amongst other elegant matters, "How Eulen-spiegel made a play in Easter fair, wherein the priest and his maid-servant fought with the boors." The oldest extant German drama was written about the middle of the 15th century, by one Hans Rosenplnet, a native of Nurnberg. He was succeeded by two fertile writers born in the same imperial city, Hans Sachs and Ayrer. Among the works of Hans Sachs we find a great number of tragedies, comedies, and spiritual and temporal histories, where the prologue and epilogue are always spoken by the herald, besides merry carnival plays; but Tieck observes that they can scarcely be reckoned as dramatic works; they are either religious or secular tales or novels, related in dialogue. All these pieces, it appears, were acted, not by players, but by respectable citizens, as an allowable relaxation, without any theatrical apparatus. The carnival plays are rather coarse, but often extremely droll, running indeed into the wildest farce, and overleaping all the bounds of reality. Ayrer, who lived at the latter end of the 16th century, among his numerous pieces, introduced many imitations or adaptations of the English drama; and during his time companies of English actors performed in various parts of Germany, particularly at Dresden.

In the first half of the 17th century, Opiz, regarded as the founder of the modern forms of German poetry, translated several tragedies from the ancients into verse, and composed operatic pastorals after the Italian manner; but it is not known whether he wrote anything expressly for the stage. Next came Andreas Gryphius, considered as the first dramatic writer of Germany. Among his imitations and translations from various modern languages, are, a tragedy from the Flemish of Vondel, and a farce called 'Peter Squenz' (Peter Quince), which is an extension of the burlesque tragedy of Pyramus and Thisbe in Shakspere's 'Midsummer Night's Dream.' But the intimacy of the Germans with the English drama seems to have suddenly ceased about this time. Gottsched, who wrote a good deal for the stage, introduced imitations and adaptations from the French on the classical model, that is, adhering to the unities; and though this was opposed by Bodmer, and some other critics, it was for a time successful. Gottsched and his players solemnly buried the German 'Hanswurst' (the clown), and Gellert and Weisse followed in his footsteps. Thus, bad translations of French plays, with pieces from Holberg, and afterwards from Goldoni, and with some feeble German imitations devoid of any peculiar spirit, may be said to have constituted the repertory of the German stage, until Lessing appeared to commence the work of redeeming it from its long-continued mediocrity.

The sceptical and analytic spirit of Lessing was, however, more successful in reforming the theory than improving the practice of the German drama. [LESSING, in BIOG. DIV.] The boldness and acuteness with which, through this medium, he attacked the prevalent French taste in tragedy were so successful, that in a short time not only the translations of French tragedies, but the German tragedies modelled after them, disappeared from the stage. He was the first in Germany who contended for the claims of Shakspere to be considered as a real and great artist, and by intelligent criticism established the study of him in his fatherland. The reform introduced by Lessing paved the way for GÖTHE and SCHILLER [BIOG. DIV.]: their success produced swarms of imitators, Iffland with his vapid comedy, Kotzebue with his sentimentality (of whose plays some have obtained a place on the English stage), and others. The great support, however, of the drama of character is the marked popularity of Shakspere, assisted as it has been by the admirable translations of Schlegel, Tieck, and others; while the French theatre supplies the afterpieces, the farces, and the operettas.

The example, however, of Göthe and Schiller, together with the admiration of Shakspere, has continually induced writers to try their strength in this field. Tieck ('Dramaturgische Blätter,' vol. i.), after commenting on the French mode of repudiating from tragedy all trivial circumstances, all reality, all national subjects, as too unideal; says, "When Shakspere first became popular in Germany, many struck out in an entirely opposite direction. They could never heap up sufficient casual circumstances, however mean, which, with all the anecdotes and speeches that they could find, they packed in all their rudeness into their tragedies, and this proceeding they styled nature." Of this school the best is G. A. von Kleist, who sinned chiefly in this assembling of trivialities, for some of his pieces, as 'Katherine of Heilbronn,' and the 'Hermannschlacht,' in other respects have considerable power. Other names are Arnim, Müllner, Halm, Theodor Körner, and Gutzkow. Arnim belonged to the romantic school, but was more successful in his novels than his dramas. Müllner was a classicist of the French school, and a copious and fluent writer. He translated, or adapted considerably, from the authors of that country, and had himself something of the light wit and invention which characterise them. In his 'Albaneserin,' a tragedy in which he endeavoured to work out a plot based on the Greek doctrine of destiny, he has violated all probability and consistency of character in working it out, but it became very popular on the public stage. F. Hahn (the pseudonym of Baron E. F. J. Münch-Bellinghausen) was of the romantic school, but his 'Griselda,' and 'Imelda Lambertazzi,' were not very successful; nor were his translations or adaptations from the Spanish drama. T. A. Körner, about 1811, wrote a number of dramatic pieces; the most noticeable were 'Zriny,' founded on the events in the life of the hero of Hungary; and 'Rosamunda,' wife of Alboin the king of the Lombards; which showed considerable promise, though combined with marks of immaturity and carelessness. Gutzkow's 'Richard Savage' is a tragedy of the domestic order; it has good passages, but little of dramatic characterisation. His comedies were better, and his 'Zopf und Schwert,' and the 'Urbild des Tartuffe,' were deservedly popular. It is remarkable that Tieck, in the work above quoted, written about 1818, mentions no modern dramatist with anything more than faint praise. Grillparzer, in his 'Ahnfrau,' and a few other pieces, has displayed a high poetic talent, with considerable dramatic power, but rather in situations than in delineation of character, though this is not altogether wanting. Except by Grillparzer, whom the Germans themselves reckon as their best dramatist since Schiller, the German tragic muse has produced nothing worthy of especial notice. Of the German opera this is hardly the place to speak, though in this they have excelled, as the names of Mozart, Beethoven, Spohr, and Meyerbeer, who are noticed in the BIOG. DIV., are sufficient evidence.

English Drama.—The period in which we find the earliest traces of the general introduction of dramatic exhibitions by the clergy throughout the spiritual empire of Rome, being that in which, under the regime of the Norman conquest, the old French language and literature had full predominance in England, and a very large proportion of its clergy were of Gallic extraction, French was necessarily the original language of our religious drama: and the first pieces that it possessed were either borrowed directly from continental writers, or were composed by the Anglo-Norman clerks in the Gallic idiom. None of the dramatic manuscripts in that language, which must have been used in England for two or three centuries after the conquest, have descended to us; but in addition to the most sufficient historical evidence of the fact, some of the miracle plays that remain in English contain the plainest internal evidence of their having been closely translated from a French original. It was not until the 36th of Edward III. that the pleadings in any of the courts of law were allowed to be made in English. At the commencement of Edward's reign (as observed by Tyrwhitt in the essay on the language and versification of Chaucer, prefixed to his edition of the 'Canterbury Tales') the French and English languages subsisted together throughout the kingdom; the higher orders, both clergy and laity, speaking almost universally French; while the lower retained the use of their native tongue, but also frequently added to it some knowledge of the other. Ralph Higden himself, the reputed author of the Chester miracle-plays as they now appear in English, bears a remarkable testimony (in his 'Polycronicon,' b. i., c. lix.) to the manner in which the English language was impaired by the children in general being still obliged at school to construe their lessons, &c. in French, by the children of the gentry being taught to speak French from their cradle, and by the anxiety of the commoners to talk French that they might be the more highly thought of.

We find religious dramas to have been regularly established performances in London as early as 1180. William Fitz-stephen, in the introduction to his Life of his friend and patron, archbishop Becket, written between 1176 and 1182, tells us that London, in lieu of the theatrical spectacles and stage plays of the Romans, to which he had just before alluded, had then a holier description of plays, in the representations of the miracles worked by holy confessors, or of the sufferings wherein the martyrs had displayed their constancy. However, from Mathew Paris ('Vitæ Abbatum') and from Bulæus ('Historia Universitatis Parisiensis') we learn that the miracle-play of 'St. Katherine' had been exhibited at Dunstable before the year 1119. According to the latter authority this play of 'St. Katherine' was not then by any means a novelty; and from a passage in the 'Annales Burtonenses,' or 'Annals of Burton Abbey,' we may infer that in the middle of the 13th century itinerant actors were well known in England.

The oldest extant specimen of a miracle-play in English is among the Harleian MSS. in the British Museum: it probably formed one of a series, and is certainly as ancient as the earlier part of the reign of Edward III.; it is founded on the 16th chapter of the apocryphal gospel of 'Nicodemus,' and relates to the descent of Christ into hell, to liberate from thence Adam, Eve, John the Baptist, and the prophets. Besides this and a few other single pieces, and a set of three plays founded on that part of the 'Acts of the Apostles' which relates to the conversion of St. Paul, there exist in this country three series of miracle-plays which go through the principal incidents of the Old and New Testaments. These are: 1. The Towneley collection, supposed to have belonged to Widkirk Abbey, the MS. of which appears to have been written about the reign of Henry VI. 2. A volume called the 'Ludus Coventriæ,' consisting of plays said to have been represented at Coventry at the festival of Corpus Christi, the MS. of which is at least as old as the reign of Henry VII. 3. The Chester Whitsun plays, of which there are two MSS. in the British Museum, one dated in 1600, the other in 1607. Several specimens of Cornish miracle-plays are extant, which differ from the English in no material characteristic but that of language.

There is abundant evidence that the Romish ecclesiastics, in their first introduction of this kind of representations, especially that part of them relating to the birth, passion, and resurrection of Christ, had the perfectly serious intention of strengthening the faith of the multitude in the fundamental doctrines of their church; and it seems the less extraordinary that they should have resorted to this expedient, when we reflect that before the invention of printing, books had no existence for the people at large. But it is no less certain that the repetition of these exhibitions rapidly worked upon the popular mind an effect which it is likely, the priestly dramatists themselves had not contemplated in the first instance: it developed the universally latent passion in the breast of social man for spectacle in general, and for dramatic spectacle especially, *for its own sake.* Here, again, was the strongest encouragement of all for the clergy to persevere in their dramatic efforts. Finding the lively pleasure which the people took in this mode of receiving religious instruction, they were tempted to add, according to their barbarous ability, embellishment after embellishment to the simple copies which they had originally presented of the most remarkable passages of Scripture story, until the profane exhibition itself, "the miracle *play*," and not the sacred subject of it, became the sole object of interest to the people who composed the audience at these representations, as, also, it became the primary object of the greater part of the ecclesiastics who took part in getting them up. These two facts are shown with the utmost clearness by the collective testimony of all the contemporary writers who have thrown a general light upon the manners of the later middle ages.

The dialogue in these productions was, for the most part, extremely rude and inartificial; and as to plot, they cannot properly be said to have had any. It is not until the middle of the 16th century that we arrive at a scriptural play having anything approaching to a regular constructed dramatic action. In this respect the series of plays which we have been considering should rather be described as a series of shows or pageants exhibited in succession, but without any artificial connection. Each of these detached divisions of the representation was indeed commonly called a "pageant;" and each succeeding play or pageant of the series was supported by a new set of performers. Thus, to get up one of these extensive sets of plays, it was necessary to provide and to prepare a large number of actors; and here we see one manifest reason why this longer class of performance was almost wholly confined, in England as well as on the continent, to the larger cities.

The seasons for exhibiting the grand scriptural plays were chiefly the Christmas and Whitsun holidays. The getting up and acting of these in the great cities early devolved upon the trading companies, each guild undertaking a portion of the performance and sustaining a share of the expense. The authentic information regarding the exhibition of the Corpus Christi plays at Coventry extends from the year 1416 to 1591, during the whole of which period there is no indication that the clergy in any way co-operated. The Chester records likewise establish that the whole management of these representations there was in the hands of laymen. From Stow's 'Chronicle' we learn that in London this class of performances was undertaken by the parish clerks (who were incorporated by Henry III.) as early as 1409; and it is remarkable that no instance is to be found of the trading companies of London having been, at any date, so engaged. The pieces were acted on temporary erections of timber, called scaffolds or stages; and it appears that in some instances they were placed upon wheels, in order that they might be removed from one part to another of a large town, and so the plays might be repeated successively in various quarters. Some of the Chester pieces required the employment of two, and even of three scaffolds, besides other contrivances: the street also must have been used, as several of the characters enter and go out on horseback. The same remark is applicable both to the Widkirk and the Coventry plays. In the latter indeed "the place" and "the mid place" are mentioned as the scene of part of the action; and it is evident from some of the stage directions, that two, three, and even four scaffolds, were erected round a centre, the performers proceeding, as occasion required, from one stage to another across "the mid place." It may be observed, too, that in one of the Widkirk plays Cain is exhibited at plough with a team of horses; and that in another it is absolutely necessary that something like the interior of a cottage should be represented, with a peasant's wife in bed, who pretends to have been just delivered of a child, which lies beside her in a cradle.

Miracle plays were acted very constantly at Chester until 1577, at Coventry until 1591, at York until late in the 16th century, at Newcastle until 1598, at Lancaster, Preston, and last of all at Kendal, in the beginning of the reign of James I. Although, in the beginning, these plays only dramatised certain scriptural events by the characters historically concerned, yet abstract impersonations found their way into them by degrees. This was perhaps done to introduce some variety into the constant repetition of the same sets of *dramatis personæ.*

Among the first innovations of this kind were the representatives of Truth, Justice, Peace, and Mercy, in the 'Parliament of Heaven,' which forms part of the eleventh play or pageant of the 'Ludus Coventriæ.' Death, in the same series, was a subsequent addition; and the Mother of Death, a still later enrichment; until at length such characters as 'Renfin' and 'Lyon' were employed, having more of individuality, but still personifying the passions supposed to have actuated the Jews against Christ. As such characters became more numerous, they interfered in a certain degree with the progress of the action; in some pieces the scriptural characters fell quite into the background; and thus, in course of time, what seems to have been at first designed as a sort of poetical embellishment to an historical drama, became a new species of drama, unconnected with history. This was called a "moral" or "moral-play," the object being to enforce and illustrate some ethical precept; for it must be observed, that the term "morality," as applied to a dramatic production, is, like "mystery," of comparatively recent introduction into our language. Some manuscript productions of this class show that moral plays were in a state of considerable advancement early in the reign of Henry VI. They seem to have reached their highest perfection under Henry VII., although they afterwards exhibited a greater degree of ingenious complication. In the reigns of Henry VII. and VIII., a company of actors usually consisted of only four or five individuals; but by doubling some of the parts, they were able to perform the greater number of the dramatic entertainments then in fashion.

Besides allegorical personages, there are two standing characters very prominent in moral-plays, the Devil and the Vice. The Devil was no doubt introduced into moral-plays from the old miracle-plays, where he had figured so amusingly that his presence was indispensable in the new species of drama. As for the Vice himself, his name appears to have been derived from the predominant nature of his character, as amidst all his varieties of form, he is constantly represented as most wicked in design.

The mechanical contrivances used for the representation of moral-plays differed in no material point from those employed in the religious exhibitions, which they gradually superseded; except that, in general, there seems to have been only one scaffold or stage, which was erected either in a street or on a green adjoining a town or village, sometimes in the public hall of a city or borough, and sometimes in a great private mansion. As an example of something between the old moralities and the later interludes of manners may be cited the "goodly interlude and merry" of John Skelton, whom Dyce regards "as one of the fathers of the English drama." In this interlude, which is entitled 'Magnificence,' and which is printed in Skelton's works (Dyce's ed. i. 225, &c.), the characters are Felicity, Liberty, Measure, Magnificence, Folly, Adversity, Despair, &c., eighteen in all, and all allegorical. Skelton also wrote two other "moral interludes," 'Nigromansir' and 'Virtue,' and what he himself in his 'Garland of Laurel' speaks of as "His comedy, Achademios called by name," but neither of these is known to exist.

The performance of moral-plays was not wholly discontinued until the end of Elizabeth's reign; and one of the last dramatic representations that she witnessed was a piece of this kind, 'The Contention between Liberality and Prodigality,' played before her in the 43rd year of her reign. Attempts had however been very early made to invest even symbolical representatives with metaphysical as well as physical peculiarities, and attract for them a personal interest; and thus it was that even in the allegorical species, the nature of which would seem to have least admitted of such modification, advances more and more decided were successively made towards individuality of character, and consequently towards the representation of actual life. Hence nearly all the later moral-plays exhibit a strange mixture of individual characters with allegorical impersonations, which, however, with all its violent incongruity, was a necessary step in the progress towards the modern drama, the drama of human passions and manners.

The first English dramatic productions in which it was attempted to exhibit sketches from actual life without any scriptural, saintly, or allegorical intermixture, belong to that class to which the denomination of *interludes*, though it has had a more general application, most properly and distinctively belongs. These pieces being, as their name imports, expressly designed for performance during the intervals of convivial entertainment, the first condition of their structure was, that the limits should be brief and the characters few. John Heywood, a musician of the households of Henry VIII. and Queen Mary, set the first example of composing interludes quite independently of allegorical materials. [HEYWOOD, JOHN, in BIOG. DIV.] He was essentially undramatic, and his humour is coarse.

The only extant English interlude from real life in which the tragic element predominates, was designed, its title tells us, to show "as well the beauty and good properties of women, as their vices and evil conditions," contrasting the character of the heroine Melibea with that of Celestina, a sort of compound of procuress and sorceress, who is hired by Melibea's lover to corrupt her, in which, after using extreme art, she succeeds; and the piece ends with exhibiting the bitter grief and repentance of the heroine. It is founded on the famous Spanish 'Celestina,' which we have already described as a long dramatic dialogue rather than a drama; but though the English piece has some vigour, it altogether wants those subtle graces which gave so wide a popularity to its foreign prototype.

'A newe, mery, and wittie comedie or enterlude, treating upon the historie of Jacob and Esau' (apparently written about 1557, but not printed till 1568), though its subject is scriptural, makes nearer advances to the structure and general character of a modern play than any piece that preceded it. In addition to the scriptural characters, it has, of the author's invention, Ragau, servant to Esau; Mido, a boy who leads blind Isaac; Hanon and Zethar, two of Isaac's neighbours; Abra, a girl who assists Rebecca; and Debora, an old nurse. Here indeed we have a five-act play, with a plot regularly constructed, characters discriminated and contrasted, and a versification, for that period, vigorous and flowing, while the comic portions of the piece have humour independent of coarseness.

The general tenor of the last-mentioned play is tragic, or at least decidedly serious. In the earliest piece of equal dimensions and regularity of structure that can properly be termed a comedy, we have also the first avowed dramatic imitation, in English, of the ancients. This is 'Ralph Roister Doister,' which was certainly in being as early as 1551, and probably written as early as the reign of Henry VIII. The former existence of such a piece had long been known, when in 1818 a printed copy was discovered, of which a limited reprint has been made. The author was Nicholas Udall. [UDALL, in BIOG. DIV.]

Another comedy, of the like dimensions and general structure, is entitled 'Misogonus;' and the author was apparently one Thomas Rychardes. The scene is laid in Italy, and the piece was probably founded on some Italian tale or play; it represents, however, the manners of England, and has many allusions to the circumstances of the day: although the plot is simple, there is much variety of situation and character; and it is worthy of remark that, under the name of *Cacurgus*, the qualities and functions of that important personage, the domestic fool, are more distinctly as well as amusingly exhibited than in almost any other of our old plays. This piece is ascertained to have been composed about 1560. It is certain that the former of these two comedies, and extremely probable that the latter, preceded the production of 'Gammer Gurton's Needle,' which all our literary and dramatic antiquaries before Mr. Collier have spoken of as the earliest English comedy, though, when it was acted at Christ's College, Cambridge, in 1566, its author, Still, afterwards bishop of Bath and Wells, was only in his twenty-third year. This however appears to be the first existing English play that was acted at either university; and it is a singular coincidence that its author should have been the very person who, many years after, when become vice-chancellor of Cambridge, was called upon to remonstrate with Queen Elizabeth's ministers against the having an English play performed before her at that university, as unbefitting its learning, dignity, and character.

The earliest extant piece in English that can now with any propriety be termed a tragedy, was written by Thomas Sackville (afterwards Lord Buckhurst and Earl of Dorset) and Thomas Norton, a barrister; and was acted before the queen at Whitehall, on the 18th of January, 1561. In the first and third printed editions it is called 'The Tragedy of Gorboduc,' from the name of a supposed ancient British king; but in the second it is entitled, more correctly, 'The Tragedy of Ferrex and Porrex,' from those of his two sons, who contend for sole possession of his kingdom after he has divided it between them. This tragedy was followed almost immediately by 'Julius Cæsar,' the earliest instance on record in which events from the Roman history were dramatised in English, although the precise nature of this performance, of which we have nothing but the mention in an old manuscript chronicle, cannot be ascertained. It is doubtful, however, whether both these pieces were not preceded by a tragedy founded on Luigi da Porto's famous tale of 'Romeo and Juliet.' From about this date until shortly after 1570, the dramatic field seems to have been pretty equally divided between the later moral-plays and the earlier attempts in tragedy, comedy and history. In some pieces of this date and a little later, as already shown, endeavours were made to reconcile or combine the two kinds of composition; but afterwards the morals generally gave way to the more popular and intelligible species of performance. We find precedence given to the latter in the licence to James Burbage and others in 1574, in its mention of "comedies, tragedies, interludes, and stage-plays;" and in the act of common council of the following year against theatrical performances in the city they are designated as "interludes, tragedies, comedies, and shows."

Still the terms tragedy and comedy, in general acceptation, remained far from the strictness of signification attached to them by the professed inculcators, by example or precept, of the imitation of the ancients. But comedy was from the beginning used in a more comprehensive sense than tragedy, being in fact very often employed as synonymous with the general designation of play. Hence it is, that Shakspere makes Hamlet, after he has had the tragedy exhibited before the king and queen, exclaim,

"For if the king like not the comedy," &c.

The vast variety of matters embraced by the dramatists of that day, and of sources from which they drew, is perfectly expressed in the prologue to the 'Royal King and Loyal Subject,' one of the earlier productions of Thomas Heywood, who became a writer for the stage some years before the death of Elizabeth; who produced, it is said, two hundred and twenty dramas; and to whom Charles Lamb gave the title of a "prose Shakspere," saying his scenes are as natural and affecting, but we miss the poet.

We have now traced the progress of the English stage from its ecclesiastical and religious origin until it became almost exclusively a mirror of actual life, and attained all those dramatic and theatrical forms which most prominently characterised the later and fuller maturity of our elder modern drama. It was in the same year, 1583, wherein Sidney wrote his 'Apology,' that Elizabeth first allowed a public company to act under her name and authority. As the dramatic writers who flourished in the brief interval between this period and that of the fullest development of Shakspere's genius, with one exception, did nothing importantly to alter or improve dramatic art, it is needless to enlarge upon their various kinds and degrees of merit which made a number of them, as Dekker, Kyd, Lodge, Greene, Lyly, Peele, Nash, Chettle, Munday, Wilson, &c., highly popular and celebrated in their own time. All who have acquired a permanent reputation will be found under their respective names in the BIOG. DIV. The single exception that we are called upon to make is in favour of Christopher Marlow, of whom we must observe, not only that his works exhibit greater vigour both of conception and of language than belongs to any of his contemporaries, but also that he was the first who established the use of blank verse upon the *public* stage, in lieu of that exclusive rhyming which possessed it before he wrote.

Of SHAKSPERE it is not necessary here to speak. A full notice of him is contained in the BIOG. DIV., besides the numerous works entirely devoted to him. Of his younger contemporaries and competitors few have transmitted a living memorial of their works to posterity; the principal are Ben Jonson, and Massinger, who are also noticed in the BIOG. DIV.; as are also Beaumont and Fletcher, who, after Shakspere, are entitled to the highest place among the romantic dramatists of England. They seem indeed to have had almost every dramatic quality short of that marvellously unerring instinct which Shakspere possessed, and which appears to be vouchsafed to few. Webster, Middleton, Marston, Massinger, Shirley, Ford, and such other of the younger contemporaries of Shakspere as we have not yet mentioned, have no characteristics sufficiently distinctive to admit of their being particularised in this general survey, though they are likewise given in the BIOG. DIV.

Such was the general condition of the stage during the reign of Charles I. down to the year 1642, when the invectives of the puritans, who had long murmured against the theatre, and at last thundered loudly against it, were changed into prohibitory law; and in 1648 not only to act plays, but even to witness them, was made a penal offence. Nearly all the players now took arms on that side the interests of which seemed identified with the existence of their own profession. Many of them perished in the field; and after the final close of the war, one company of actors only was formed out of the remains of all the former ones, and occasionally, with great circumspection, performed at private mansions in the vicinity of London.

Davenant as manager, and Betterton as actor, form a slender link of connection between the old stage and that of the Restoration. Charles II. being considered, in his relation to the theatre, as a sort of restoring and tutelar deity, its character was now formed in absolute deference to the half foreign and wholly vicious taste of himself and his courtiers. Under these auspices, Davenant introduced the Italian system of decoration, the *costume* as then understood, the opera music, and the use of the orchestra in general. A still more important innovation in theatrical arrangements was, the permanent adoption of the practice, against which the puritans had directed the most violent of their anti-dramatic fury, but which had long been established in Italy, Spain, and France, of having the female parts personated by women instead of boys. The result of this great neglect of the old dramatic and theatrical system of England, and assiduous study of that of France, was, for a long period, an almost entire denationalisation, both in form and spirit, of the current dramatic literature. Davenant himself, who had resided very much in Paris, seems to have acquired this exotic taste long before the Restoration, as it is fully exhibited, amongst others of his productions, in his operatic piece, 'The Siege of Rhodes,' performed as early as 1656. Hence, in the theatrical restoration which accompanied the political, he set himself cordially to work, by altering old pieces, and writing new plays, operas, prologues, &c., to contribute towards the furnishing of that new theatrical repertory which the new dramatic system required. Of all his works, however, nothing has escaped a merited oblivion.

It was left for the industry and fertility of Dryden to give the new theatre a thorough establishment according to the new ideas, a task to which he applied himself with all possible diligence both by example and precept. [DRYDEN, in BIOG. DIV.] The drama hence became a compound of the extreme licence of the later writers of the early English school, with the conventionality of the French, but without the vigour of the one or the vivacity of the other. The Duke of Buckingham, who, amongst other vigorous though wayward and generally misapplied talents, possessed high powers of ridicule, undertook to satirise these faults and absurdities of Dryden and his school, in his comedy of 'The Rehearsal,' wherein, although the structure of the piece itself might have been more artificial and diversified, the separate parodies are very ingenious and effective.

But the best-aimed satire, though it might correct in some degree could not regenerate the stage. This could have been done only by the arising of some greater and more genuine dramatic genius, or at least by the successful appearance of some very great actor, capable of entering fully into the spirit of the elder drama. 'The Rehearsal' might indeed contribute to produce that nearer approach to nature which, among the compositions of Dryden's younger contemporaries, has preserved upon the stage one tragedy of Lee's and two of Otway's. Shadwell's seventeen comedies, though he affected to imitate Ben Jonson in exhibiting humorous and eccentric peculiarities of character, are deservedly forgotten. Wycherley, so much in favour both with Buckingham and King Charles, and afterwards with King James, had much more genuine pretensions to the higher and more vigorous order of comic power [WYCHERLEY, in BIOG. DIV.], and Congreve deserves to be considered as the true father of "genteel comedy" on the English stage, and was long regarded as the great model for imitation in that department. [CONGREVE, in BIOG. DIV.] All these writers, however, are objectionable for their licentiousness, which, though the representation may have been a correct picture of the manners of the time, very soon banished them from general exhibition or reading.

The continuance of this moral depravation of the drama produced at length, in 1698, a severe castigation from the pen of the sturdy nonjuror, Jeremy Collier, under the title of 'A short View of the Immorality and Profaneness of the English Stage, together with the Sense of Antiquity on this Argument.' In this work, its author, armed with sufficient learning and sarcastic wit, attacked all the living dramatists from Dryden to D'Urfey; and although some of them, including Congreve, less candid on this occasion than Dryden himself, set up a petulant and sophistical defence, yet this publication of Collier's had a permanent effect on the stage as well as on the public mind. This effect, however, was operated only by degrees. Vanbrugh followed in the line of Congreve, and, in spite of Collier's animadversions, did so with little more regard either to morality or decorum, though mingling more humour with his wit. His contemporary, Farquhar, though displaying sufficient libertinism of language and sentiment, did not carry them to so gross an excess. The Restoration period of English theatrical history had not only brought female performers for the first time before the public, but female dramatists also. The numerous comedies of Mrs. Behn, who wrote under Charles II., are remarkable only for the full share which they possess of the licentiousness of her time. But in Mrs. Centlivre, a prolific writer of comedy, exactly contemporary with Farquhar, we find more genuine dramatic talent, yet exhibited much more in a lively bustle of intrigue than in forcible delineation of character. Just at the same period, also, Steele, among the other various exertions of his pen, wrote for the stage in a kindred spirit with Farquhar, but with inferior dramatic skill; and Cibber produced his best comedies, 'The Careless Husband,' and 'The Nonjuror.' Fielding, the novelist, commenced his literary career as a writer of comedy; he chiefly demands notice in dramatic history as one of the principal of those writers for the stage who afforded Sir Robert Walpole a pretext for obtaining the act to limit the number of theatres, and subject dramatic performances to the lord chamberlain's license. In a very similar predicament was Gay, after the appearance, in 1727, of his 'Beggars' Opera.' Its professed object was, by way of burlesque, to ridicule the Italian Opera, which had been established and maintained at great expense, and was thought by many to be rising in hurtful rivalry with the national drama. But amidst the general satire on political and fashionable selfishness and depravity which this composition implied, the persons then in power took so much of it to themselves, that while 'The Beggars' Opera' had the unprecedented run of sixty-three successive nights, and transformed the actress who represented the heroine into a duchess, the lord chamberlain refused to license for performance a second part of it entitled 'Polly.' This celebrated production, however, though still a standing favourite with the public, is now chiefly remarkable in dramatic history as the prototype (unwittingly, it seems, on its author's part) of a new species of dramatic composition upon the British stage, since known as 'the English opera.'

We must now revert for a moment to the history of modern English tragedy. After the example of Lee and Otway, Southern and Rowe endeavoured to return to a more natural tragic tone and style than those which Dryden had so long practised and inculcated. Addison's 'Cato,' notwithstanding the great temporary celebrity and popularity which party rivalry conferred upon it, merits no attention in the history of dramatic art, except as having been the first, and, it should seem, the model, of a series of the most frigid productions in imitation of the French classic school, by Young, Johnson, Thomson, Glover, &c., that are to be found in our literary history. With some small poetic, they have no dramatic pretensions; yet the very excess of their formality and frigidity perhaps contributed to that decisive reaction of the public mind in favour of the elder dramatic school, which took place in the middle of the last century, and which now demands our attention.

Garrick's restoration of Shakspere to his rightful supremacy over the English theatre was a combination, upon a more extensive scale, of the efforts in the same direction which had been made by Betterton. The success of Garrick contributed much to that more general appreciation of Shakspere which gradually went on increasing. This appreciation, which was not a mere passing fashion, was nothing less than the removal of one great mark, worn for eighty years before, of national degradation, morally and intellectually. Had any such actor as Garrick existed at the restoraton of Charles II., he might probably have done much to prevent the wretched denationalisation of the theatre which was so much favoured by that king's exotic and vitiated taste.

Garrick himself, having made no great attempt in dramatic composition, exposed himself to no considerable failure: one or two of his small afterpieces have kept possession of the stage; but his labour of this kind most worthy of mention is probably the share which he took in the composition of one of Colman's best comedies, 'The Clandestine Marriage.' Cumberland's comic powers were respectable; but in his most successful pieces, 'The West Indian,' brought out by Garrick in 1771, and 'The Wheel of Fortune,' to which John Kemble's masterly personation of the principal character gave so decided a popularity, he scarcely rises above mediocrity. Horace Walpole's tragedy, 'The Mysterious Mother,' though its subject necessarily excluded it from representation, set the first example of a vigorous attempt to return to a natural and healthy tragic tone and style. As for the 'Douglas' of Home, it has no such qualities to recommend it, but acquired and has retained the public favour chiefly by dint of one truly and deeply pathetic situation wherein the strongest domestic affections are profoundly and permanently interested. Sheridan gave new life and spirit to "genteel comedy," in which department he remains at the head of the writers of the present era. Though perhaps his pieces are less perfectly finished than those of Congreve, already characterised as the chief of this class of dramatists in the preceding period, and although, especially in 'The School for Scandal,' he is subject to the same imputation as his predecessor, of being too indiscriminately lavish of epigrammatic wit, yet he has more truly comic wit, more force of genuine humour, than Congreve, as is more particularly felt in his play of 'The Rivals,' and should therefore, we conceive, be ranked above him as regards the more essential qualities of comedy, The dramatic merits of Goldsmith were of a totally different cast: a certain eccentric drollery of character and whimsical extravagance of plot are the distinctive characteristics of his two comedies, one of which, though by no means among the most excellent productions of his pen, has kept an honourable place in the public favour. Of the elder Colman's pieces, two, 'The Jealous Wife' and 'The Clandestine Marriage,' are still deservedly esteemed; and the latter in particular is frequently acted: they combine much elegance of composition with considerable comic power. Nor among the comic dramatists of the latter half of the last century must we forget to mention the once celebrated Samuel Foote, who has been more commonly than appropriately called the English Aristophanes, seeing that such a designation conveys much too high a compliment to Foote, and a very indifferent one to the great master of the elder Grecian comedy. So little had Foote's pieces of that burlesque ideality which constituted the essential character of the latter, that his exercise of the *vis comica* reduced itself almost exclusively to a contemporary personal satire, amounting to little more than a refined species of mimicry, which, from the merest mercenary motives, he directed quite as readily against the most innocent peculiarities of living individuals as against the most injurious vices or follies. Hence it is, that of the many farces which he wrote, chiefly to exhibit in them his own powers of satirical mimicry as an actor, not more than one survives upon the stage.

It was towards the close of the century that the sentimental comedy of the German school of Kotzebue, with little but its novelty to recommend it, acquired a footing in England. In this kind, among the direct adaptations from the German, 'The Stranger' has had the most general success, and is the most perfect representative of the species. Among the native efforts in the same line, Holcroft's 'Road to Ruin' is still popular. The same writer has the credit also of having first introduced on the English stage the melo-drama, which has since filled so large a place upon it. Mrs. Inchbald, among many pleasing original pieces in the lighter comedy, has likewise given us an adaptation from Kotzebue. Tobin's 'Honeymoon' still holds possession of the stage. Morton, with too much of the German sentimentality has considerable humour, and sketches character and manners with frequent success. Kenny and O'Keefe also produced a few comedies and farces of more than average merit. M. G. Lewis, in his tragedies, as in his romances, drew from a very different German source, in his taste, we might almost say his rage, for the marvellous and the terrific. A kindred spirit is displayed in the late Charles Maturin's tragedy of 'Bertram.' As regards Lord Byron's tragedies, we have only to remind the reader that as their author never designed them for representation, he is by no means chargeable with their dramatic failure.

We abstain from individual criticism of living English contemporaries. As regards modern efforts in the Shakspearian drama, the flight in this case is so lofty and so bold, that even to attempt it may be said to require almost as vigorous and as rare a genius as to succeed. But on the ground next in elevation, that of tragedy in the more limited sense, aspirants, if not very numerous, are still, from time to time, presenting themselves: however, we have not yet anything that approaches in natural vigour or in poetic richness, either to the masterpieces of Schiller, or even to the most successful efforts of the new romantic school of France. In the higher comedy the experiments are yet more rare. Decency has long been thoroughly established in this department; but since Sheridan's time, we have very few comedies in which we may look for the raciness of humour, the brilliancy of wit, or the happiness of invention which seasoned the licentiousness of our earlier comic writers. Of the occasional pieces written to show off the talent of particular actors, the numerous adaptations of French farces and vaudevilles, and the many trifles that are continually coming forth into an ephemeral popularity in the form of comic opera or burletta, we shall merely remark that, with much that is lively and amusing, they have little that indicates either vigour or originality of dramatic talent.

DRAMATIC LITERARY PROPERTY. [Copyright.]

DRASTICS. [Cathartics.]

DRAWBACK, in commerce, is a term used to signify the sum paid back by government on the re-exportation of goods, upon the importation of which an equal sum has already been paid as duty. The object of this repayment is to enable the exporter to sell his goods in foreign markets unburdened with duties; and it is clear that if duties are required to be paid on the first importation, no transit trade can be possibly carried on unless drawback is allowed by the government. Payments of this nature, although they are sometimes confounded with bounties, are in principle essentially different from them. [Bounty.] Previous to the establishing of the warehousing system in this country in 1803, and when the payment of duties on all foreign and colonial merchandise, with the exception of tobacco and East India goods, was required on the first importation, drawbacks were in all cases allowed upon re-exportation. This course was injurious, not only to trade, but also to the revenue. Goods may now be warehoused, and the duty is only paid when withdrawn for home consumption; but drawbacks are allowed on articles, such as paper whether printed or plain, which have paid an excise duty.

DRAWBRIDGE is a moveable description of bridge used in ancient castles and in modern fortresses, the object being to obtain a secure means of communication across a river, canal, or ditch, with the means of cutting off that communication when necessary, in order to prevent the enemy using it to gain access to the place, and in the two former instances to permit the passage of vessels. Drawbridges are ordinarily of one of the three following kinds: 1. Bascule, Balance, or Lifting; 2. Turning or Swivel; 3. Rolling.

The first is the description of drawbridge that was commonly used in old castles and fortresses, and in its simplest form consists of a platform turning on a pivot or hinge in the escarp wall, and raised by means of chains attached to the other end of the bridge, passing over pulleys in the archway which gives access to the bridge.

The swivel or turning bridge may be formed in either one or two leaves, each leaf turning horizontally on a pivot firmly fixed in the bank, on which it rests when open; the end of the bridge having rollers to let it move more freely.

The roller bridge consists of a platform which is pushed forward, or withdrawn, by means of a pinion working in a rack on the under side of the platform, with friction rollers to render the work easier.

(For further particulars, see *Aide Mémoire to the Military Sciences*, from which the above has principally been taken.)

In civil engineering, draw-bridges are most frequently used upon canals, rivers, or in docks; and their construction is mainly regulated by the character of the navigation they are intended to accommodate, even to a greater extent than by that of the traffic over the bridge itself. The conditions which draw-bridges should fulfil are, in fact,—1, that they should be strong and steady; 2, that they should be rapidly and easily opened; and 3, that they should not interfere with the passage of the boats, or other craft, they are designed to pass. According, therefore, to the class of vessel so passing, the machinery by which the bridge is raised may be either above or below the floor-line; or the bridge may be either a *turning*, or a *bascule*, or a *rolling* bridge.

Upon canals, or rivers exclusively used for inland navigation by means of barges, there can be little reason for adopting anything but the old-fashioned Dutch lifting-bridge, in which the end of the lifting part of the floor is connected by means of chains to the extremity of a system of levers and counterpoises, and bearing at the opposite end to the bridge suspension-chains, a chain with handles, for the purpose of pulling down the counterpoise. This kind of lifting-bridge presents the advantages of being easily opened, and, from the fact of its machinery being raised above the floor line, of requiring but slight elevation above the water-way, and thus dispensing with the necessity for long raised approaches. However, it is found to be objectionable in cases where masted craft pass, and even to entail some inconvenience in the navigation of rivers by steam boats. Lifting bridges are therefore exclusively reserved for canals, or for such rivers as those which traverse the towns of Holland and Belgium. From the fact of their requiring only light foundations, these bridges are peculiarly applicable in soft alluvial plains.

Turning bridges are those most frequently used in docks, basins, or canals resorted to by masted vessels; because they fold back out of the way of the masts and yards, and also interfere in the least dangerous manner with the quay roads or walls. They are, however, very costly in themselves, and they require very expensive foundations. Upon some of the modern railways turning-bridges are introduced, by means of which two water passages are opened, the bridge itself turning upon a central pivot.

Bascule bridges were frequently used about the end of the last century for dock and river communications, as at Hull, Havre, &c.; but at the present day they are avoided, because it is found that the platform of the bridges stands in the way of the yards or the standing rigging of ships passing through the locks to which these bridges are attached. The same objection applies to the cost of the foundations and of the machinery of Bascule bridges as to those of the more commodious turning-bridges.

Rolling-bridges are used when it is not possible to construct above ground any machinery for lifting the platforms, and there are local difficulties in the way of executing the foundations of either of the other sort of draw-bridges. The manipulation of these rolling-bridges is, however, very complicated. A filling-in piece of the roadway, as wide as the opening it is desired to leave, is first rolled laterally, and then the bridge itself is rolled back into its place. The framing of the bridge is also costly; for during the time that the platform is being rolled back its end is without support, and it acts to cause deflection with a very long lever, thus entailing the necessity of a strong framing. Nevertheless, there are such manifest advantages in the introduction of rolling-bridges, when, if they were not employed, it would be necessary to resort to the use of the other descriptions of such structures as would require loftier approaches, that they are frequently used in railway, or even in dock works. The largest bridge of this description lately executed is the one erected to carry the railway over the Arun, near Arundel. The largest turning-bridge is the one carrying the railway over the Wornsum, in the county of Norfolk. It is to be observed, that railway engineers have, however, great objections to the use of draw-bridges of any kind, and that they are only resorted to in the last extremity.

DRAWER. [Bill of Exchange.]

DRAWING, in its strict meaning, is the art of representing objects on a flat surface by lines describing their forms and contours alone, independently of colour or even shadow. But shadow is closely allied with drawing, both in practice and in theory; because, notwithstanding that form may be clearly expressed by outline alone, shadow, while it gives surface and substance, is dependent upon form, and in many cases requires to be accurately defined according to the rules of perspective. More particularly is this the case when shadows are cast from any regularly-shaped body upon one or more planes; as, for instance, the shadow from a column upon a flight of steps, or that of a man upon the ground and a wall. It is true that, except in geometrical forms with sharp edges, very few such lines exist in nature, outline being no more than the boundary of surfaces as it exhibits itself to the eye. Thus, in the case of a globe or a cylinder, there are no lines whatever in the one, no edges down the latter; their outline being not on any part, but merely the termination of that portion of it which is visible. The same holds good with respect to the human form, and to that of animals, whose limbs have no determined edges, but consist of parts more or less curved, and even when nearly flat never stopping so as to form a specific line or positive edge. The outline of the superficies will consequently vary according to the direction in which the object itself is viewed.

Although drawing embraces all objects and their forms, in its more restricted technical sense it is generally understood to imply the drawing of the human figure, as that species of it which is the most scientific in itself and the most important in art. But correct drawing is none the less necessary for other objects which it is the province of the artist to represent. Landscape painting, it has sometimes been said, requires comparatively little skill in drawing and no great exactness of hand, since the forms it deals with, such as those of trees, mountains, rocks, &c., being altogether irregular, general fidelity as to form is sufficient; while fidelity of colouring and aerial perspective, and the effect of light, are the qualities most essential to it. But this fallacy, which has misled many young landscape students, must be discarded by him who wishes to paint landscape worthily. It is however true, that it requires greater expertness and decision to draw correctly even a statue than a tree or a mountain; the nicest observation of all the proportions, the most scrupulous attention to every lineament, to every minute detail, to every marking, every gradation of shadow, however slight, are here in fact indispensable. Yet in such case the draftsman has nothing more to do than patiently copy a perfectly immovable object. Far more arduous than such task is that of representing similar forms taken from the living subject. Here, unless he be also well disciplined and grounded in anatomical knowledge, the best models will avail him little save as studies of proportion, and of such positions and attitudes as, although they are intended to express motion, can yet be preserved for a considerable time. He may, indeed, thus perfect himself in that particular species of anatomical perspective which is termed foreshortening, and he may do much in the way of training both his hand and his eye, but for direct action and motion his model will serve only to inform him what muscles they are that are brought more forcibly into play, and other transitory phenomena which disappear almost as soon as they exhibit themselves. Indeed, some motions are so exceedingly rapid and fugitive that they cannot be drawn, and can hardly be studied from the life, but if attempted to be shown in painting must be represented according to theory, based upon exact anatomical knowledge. Some attitudes and motions are either so exceedingly evanescent, as those of the figures hurled down in Rubens' picture of the Fallen Angels, or so purely imaginary, as when angels or winged genii are represented hovering in the air, that such theory alone will enable the artist to express them with any degree of apparent fidelity. The extremities—that is, hands and feet—are among the most difficult parts of the figure, and require great practice in drawing. Drapery, again, is, next to the figure itself, of the greatest importance, while it is less reducible to any positive rules for disposing it.

In order to attain to a complete mastery of the human figure, which after all is to be regarded only as the means to a higher aim, and the mechanical apparatus for effecting it, it is necessary to commence by studying what is tedious in itself, and seems almost foreign to the artist's purpose, namely, the internal configuration of the human frame. It is not enough to understand the proportions of the body and limbs, with the form and situation of the external muscles, but it is necessary that all the muscles, their purposes and functions, should be well understood. Nor must osteology, or the bones of the skeleton, be neglected. Indeed it is desirable that the artist should be able to draw the skeleton figure in any attitude, by which his figures will always be well put together. The drawings of Raffaelle and Michel Angelo show that those great masters, even when at the summit of their fame, used frequently to draw the skeleton of the more important figures of their compositions. By way of practice in this respect, it has been judiciously recommended that as soon as he is a perfect master of the skeleton, the student should proceed to draw antique statues in that state, afterwards clothing them with muscles, as in the marble or cast before him. But it is necessary to study muscular action with even more zeal and accuracy than the skeleton. Without scientific knowledge of muscular action, the painter will be able to give his figures only attitudes, and those not always correct, should he have occasion to represent such as from their nature do not admit of being copied from the life. Again, unless, besides possessing a complete knowledge of the human body and the action of the limbs and muscles, he is also able to express the emotions of the mind, and that not as they display themselves in the countenance alone, but in gesture, attitude, and the whole frame, he will at the best produce only clever academical figures, skilfully drawn, but devoid of soul and sentiment. He must therefore endeavour to make himself master of expression, in the most comprehensive meaning of that very arduous and complex study, which, be it observed, depends entirely upon drawing and truth of delineation. For this purpose such works may be recommended as Bell's 'Anatomy of Expression.'

Perspective, which is generally treated of separately, and is therefore ordinarily considered a distinct study, is nevertheless a most essential part of drawing,—in fact its very grammar, all objects being subject to its laws, although they may not admit of being delineated according to the processes employed for drawing buildings, furniture, and such things as consist of strict geometrical forms. Reserving the science itself for the article Perspective, we only advert to it here in order to press upon the student its essential and primary importance; and that, instead of being an extraneous accomplishment, it is inseparably connected with drawing; for perspective is based upon the laws of vision, and consists of practical rules deduced from those laws.

The student then would do well to exercise himself thoroughly in drawing before he proceeds to colour; and the longer he confines himself to outline, with no other degree of shadow than what is necessary to express the character, the substance, or texture, and the different prominences or depressions in the superficies of objects, the more likely will he be to attain precision and correctness, as there will be nothing to conceal vagueness and inaccuracy of form, but form will be exhibited undisguisedly either in its beauty or the reverse. One great step towards correctness is to understand perfectly beforehand the object to be represented, its character both general and specific; when this is the case, the hand, supposing it to be sufficiently well trained, readily obeys the eye and the mind. Constant observation, therefore, and as careful an examination of objects as if he were preparing to draw them, will greatly promote the student's advancement, and he will be really learning, when, because he is not actually at work with his pencil, he may seem to be doing nothing. And this applies equally to the student of scenery as of the figure. The more distinct and even scientific be his knowledge of nature and natural phenomena, the more truly and confidently will he be able to represent the appearances of nature; the wider his range of observation, the more likely will he be to avoid mannerism as well as to escape from signal mistakes.

We have spoken hitherto of the necessity of drawing accurately to the art-student, but drawing, as far as regards facility in delineating common forms and objects so as to enable a person to describe them promptly with the pencil, ought to be considered nearly as indispensable a part of education as writing itself. By this, such a degree of proficiency is meant as would enable a person either to express or explain his ideas upon paper, or to sketch from nature. Sketching, in the more popular meaning of the term, implies little more than the act of writing down in a kind of graphic shorthand the characteristic lineaments of a landscape or any individual object, an acquirement little more than mechanical, and which stands in about the same relationship to drawing, in its more elevated character, as an ordinary letter does to a finished literary composition. Like the sketcher, the draftsman only copies the objects before him, and those generally inanimate ones; but with this difference, that his drawings are expected to exhibit perfect fidelity, and admit of being worked up to a high degree of finish and beauty.

There are various manipulations or modes of drawing, distinguished according to the materials or implements made use of, such as chalk, black lead pencil, sepia, or other tinted drawings; which last-mentioned class are sometimes called washed drawings, in which some indication of colouring is occasionally introduced. But what is termed water-colour drawing, as now practised, is altogether a species of painting, although the process is totally different from that of oil colours, or even distemper. Pen and ink drawings in the style of etchings, either with or without the addition of wash of shadow, are capable of producing considerable effect. Still more effective are drawings either in black-lead pencil, chalk, or sepia, made on paper of a neutral tint, the bright lights being put on with white.

Painters' drawings or studies, such as those of the old masters, are highly valuable because they often exhibit their first conceptions in all their energy, and admit us to immediate intercourse, as it were, with their ideas as they arose in their minds. Collections of such drawings are found in most national and royal, and in many private, museums. The British Museum contains a very choice though not very extensive collection of drawings by the old masters. Perhaps the finest ever formed by a private individual was that of Sir Thomas Lawrence, P.R.A.; but it was dispersed after his death. The bulk of the Michel Angelo and Raffaelle drawings were purchased for Oxford University, and are kept in the University galleries. Of late, photography has been applied to the production of fac-similes of the drawings of painters, especially those of the old masters; and, the application ranks among the most interesting and valuable of that beautiful art. The art branch of the Department of Science and Art have therefore conferred a great boon on students of art by making photographic fac-similes of the exquisite drawings by Raffaelle in the British Museum, the Louvre, and especially the unrivalled collection belonging to the University of Oxford, and issuing them at almost nominal prices.

DREAMS may be best described, in a few words, as trains of ideas presenting themselves to the mind during sleep. The person to whose mind ideas present themselves in trains during sleep, is said *to dream*, and the word *dreaming* designates either the state of the mind in dreams, or else the susceptibility or potentiality of having dreams. We use the word in the former sense, when we speak of "the state of dreaming;" in the latter, when we say that "dreaming is a part of man's nature."

It is the principal design of this article to present the reader with the *psychological* theory of dreams: to explain, first, the psychological law by which dreams, as being trains of ideas, are regulated, and to exemplify the operation of this law; and, secondly, by means of this law and of certain psychological circumstances peculiar to the state of sleep, to explain the differences existing between dreams, as being trains of ideas which occur in the state of sleep, and trains of ideas as they generally occur in the waking state. When dreams, as psychological phenomena, shall have been thus explained (in the scholastic phrase) *per genus et differentiam*, the reader will be in possession of the whole psychological theory of dreams.

But dreams may give rise, as they frequently have given rise, to an inquiry other than the psychological inquiry which we have indicated, namely, one which in common speech is called a *physical*, but which would be better called, by coining a word analogous to psychological, *somatological* inquiry. Besides observing the mental phenomena of dreams, and referring these phenomena to a mental or (as we have before termed it) psychological law, together with certain psychological circumstances peculiar to the state of sleep, men may speculate on the manner in which the state of the body in sleep affects the mind—how the body when asleep is affected, and how again the body thus affected operates to the production of the phenomena of dreams. Of this physical or somatological inquiry, the greater and more important part, that which relates to the state of the body, belongs properly to the subject of sleep; while, as regards the manner in which the state of the body operates to the production of the phenomena of dreams, to determine which observation gives very small assistance, we shall state, in a second division of this article, the little that can be relied on.

In the third part of the article we shall give a few well-attested instances of dreams, accompanied by circumstances which, as they are related, do not seem to admit of explanation. And this will lead us naturally to say a few words concerning the supernatural character which, at different times and in different countries, has been attributed to dreams.

I. We have said that dreams are trains of ideas presenting themselves to the mind during sleep. Occasionally, and under peculiar and definable circumstances, *sensations* are felt during sleep; some of which commonly do not awake the dreamer, while others, which awake him, are yet shown to have been felt during sleep by the circumstance that a train of ideas called up by them passes before the mind, invested with the attributes of dreams, in an interval between the sensation and the waking. These sensations, however, are, from the nature of the case, comparatively so few, and, even when they are felt, so unimportant in comparison with the ideas which they call up, that they may very well be excluded from notice in a general description of dreams.

Bearing in mind then the existence of these few and unimportant exceptions, we shall henceforward speak of dreams as consisting only of ideas. And that the feelings composing dreams, which are at the time believed to be sensations, are not sensations, but only ideas,—that we do not see, hear, smell, taste, and touch what we believe at the time that we respectively see, hear, smell, taste, and touch, but that we only have the ideas of these respective sensations, cannot need proof. At any rate, the only proof which the nature of the case admits is one to be furnished by each individual for himself. Knowing the circumstances which, when he is awake, are concomitant with the having the feelings called *sensations*, and the circumstances which are concomitant with the state of sleep and of dreaming,—knowing further that these two sets of circumstances are incompatible with one another; while, on the other hand, the circumstances concomitant, when he is awake, with the having the feelings called *ideas*, are such that he may very well have them likewise when he is asleep; he cannot but conclude for himself (and if he do not, other means of proving it to him there are none) that the feelings of which he is conscious during sleep are not, as at the time he believes them to be, sensations, but ideas. He knows that when he is asleep and dreams, he is so situated that he cannot have the sensations which at the time he believes that he has. He knows that he *may*, in his then situation, have ideas; and, if he has any feelings at all, *must* have ideas. He must conclude then that what at the time he believes to be sensations are in reality only ideas, and must consider the appearance of these ideas as sensations, as a matter to be explained by means of psychological circumstances peculiar to the state of sleep.

Dreams, then, being thus assumed to be trains of ideas, we proceed to investigate the law by which they are regulated, and to exemplify the operation of the law.

On observing, or (to use the phrase which, when mental phenomena are spoken of, is more common) reflecting upon, our waking train of ideas, we find that when two sensations, or two ideas, or a sensation and an idea have occurred in proximate succession, the sensation that occurred first, or its idea, or the idea that occurred first, is afterwards followed by the idea of the sensation that occurred second, or (as the case may be) by the idea that occurred second, and that this happens the more surely in proportion as such proximate succession of the two sensations, or two ideas, or sensation and idea, has been more recent, and in proportion as it has been more frequent. Such is a brief statement of what is called the law of association, and of its laws. [ASSOCIATION.]

"When a man thinketh on any thing whatsoever," says Hobbes, "his next thought after is not altogether so casual as it seems to be. Not every thought to every thought succeeds indifferently. But as we have no imagination (idea), whereof we have not formerly had sense in whole or in parts; so we have no transition from one imagination to another, whereof we never had the like before in our senses." ('Leviathan,' i. 3.) Hobbes has here enunciated the principle of previous proximate succession, or contiguity (whatever it may be called), and has spoken of it as the sole primary principle of association; the only defect in the manner in which he has enunciated it being the omission of the instances of two ideas, and of a sensation and idea occurring in proximate succession. Most subsequent writers on the subject have added other primary principles, more or less, to this one enunciated by Hobbes; and in so doing are, we think, chargeable with an imperfect analysis. Mr. Hume enumerated three principles, contiguity in time and place, causation, and resemblance; a fourth, contrast, which he named, he looked upon as a secondary principle resolvable into causation and resemblance. ('Essays,' vol. ii., p. 21.) Dr. Brown, finding great fault with Mr. Hume's enumeration, and observing that all suggestion (the phrase employed by him in the place of association) depends on prior co-existence (by which he means the same as we by proximate succession), nevertheless does not seem to have perceived the processes by which resemblance and contrast may be resolved into this principle, and furthermore treats the topic under the threefold division of resemblance, contrast, and contiguity in place or time, all which he inconsistently calls primary principles. ('Lect,' 34 foll.) Mr. Mill has two principles, subdivisions (and perhaps unnecessary subdivisions) of the one principle, as it is represented by Hume and Brown, contiguity; he calls them the "synchronous order," which, he says, answers to contiguity in place, and the "successive order," which, he says, answers to contiguity in time. ('Analysis of the Human Mind,' vol. i. p. 53.) He observes rightly, that the principles of causation, resemblance, and contrast, may be resolved into previous proximate succession; though he does not go through the analyses, and indeed the few hints which he gives of what he deems the necessary processes seem to show that he did not understand them.

The mode of resolving causation is obvious; causation indeed is but a name for previous proximate succession, under particular circumstances. Let us briefly explain (Mr. Mill not having done it) the modes of resolving resemblance and contrast into the same principle; taking, which is the most convenient method in such cases, a particular instance of each.

The sight of a man, A, calls up the idea of another man, B, who resembles him. Some of the sensations and ideas which are elements of the complex feeling called *the sight of A*, have been before present to the mind as elements of the complex feeling called *the sight of B*; and these sensations and ideas call up the ideas of the other sensations and the other ideas which go to make up the complex feeling called *the sight of B*, and which are not elements of the complex feeling called *the sight of A*; for with these other sensations and other ideas they have before existed in proximate succession, or (as we may say for shortness) have co-existed. These ideas, thus called up, co-exist (as we may again say for shortness) with the ideas of the sensations, and with the ideas, which, belonging both to the sight of A and the sight of B, called them up; and thus the idea of the sight of B, or the idea of B, is present to the mind.

Again, as regards contrast, the idea of a giant calls up the idea of a dwarf. One idea that is an element of the complex feeling called *the idea of a giant* is the idea of tallness, which idea is made up of the idea of height and that of greatness. The idea of tallness, and therefore that of height, is a vivid idea, or (changing the phrase) it is an idea on which the mind dwells, or which very frequently presents itself to the mind when a giant is being thought of; and so when a dwarf is being thought of, is the idea of shortness, which again includes the idea of height, a vivid idea. Now the idea of height being a vivid idea, or one which very frequently presents itself to the mind when a dwarf is thought of, is strongly (and strongly by reason of the frequent proximate succession of the two ideas) associated with the idea of a dwarf, as it is, for the same reason, strongly associated with the idea of a giant. The idea of the giant then calls up the idea of height, which has frequently before (as we may say for shortness) co-existed with the idea of the giant; and the idea of height thus called up, calls up, for the same reason, the idea of the dwarf.

We have dwelt thus at length on the psychological law of association, and its primary principle of previous proximate succession, because it may be said to be the key to the whole psychological theory of dreams. This law being fully comprehended at the outset, so much of the remainder of our task as consists in the exemplification of its mode of operation is made straightforward and easy.

We arrive at the law of association, as determining waking trains of ideas, by the processes of observation and of induction. We may either extend the law, thus arrived at in the case of waking trains of ideas, to the case of dreams, knowing independently that these are made up of ideas and are therefore not different in kind from waking trains; or again we may arrive at the law, in the case of dreams separately, by the same processes of observation and induction. The former mode is as satisfactory as the latter; and in the way of this latter there are many difficulties, arising out of the nature of the case, which do not exist as regards the former. By the former mode, therefore, which is the easier, and which is at the same time logically correct, we come to the conclusion that, in dreams, one idea is followed by another idea, when either the sensation of which the first is the copy has, at a previous time or times, been followed by the sensation of which the second is the copy, or when one of the ideas has followed or been followed by (as the case may be) the sensation of which the other is the copy, or again when the ideas themselves have been, at a previous time or times, present to the mind in proximate succession; and that this happens the more surely, or (changing the phrase) the association between the two ideas is the more strong, in proportion as the previous proximate succession has been more recent, and in proportion as it has been more frequent. Of the law thus modified by the circumstances of recency and frequency, *causation*, *resemblance*, and *contrast*, are names for classes of instances; and in dreams, as in waking trains, the idea of what is called a cause is generally followed by the idea of what is called its effect; the idea of an object which resembles another object is generally followed by the idea of the object which it resembles; and the idea of an object which is said to be contrasted with another object is sometimes followed by the object with which it is said to be contrasted. We will now exemplify, with somewhat more particularity, the operation of this law of association in dreams.

1. The classes of associations which make up the greater part of our mental history when we are awake, those concerned in naming, in classification and abstraction, in memory, in belief, in reasoning (whether to ourselves or by word of mouth, or in writing), in imagination, in desires and aversions, in affections, occur likewise during sleep, and make up a considerable part of our mental history in sleep, that is, of our dreams. It will not be necessary to give instances of the occurrence of each of these classes of associations, as every one who is conscious of having dreamed must be conscious of having had these several states of mind during his dreams. And further, the giving of the instances would be of little use, unless the instances given of the several states of mind were analysed, and the associations forming these several states of mind set forth in the particular instances given; but this, even were it relevant to our present purpose, would carry us to an unreasonable length. Referring the reader then to Mr. Mill's masterly work, entitled the 'Analysis of the Human Mind,' in which the working of the law of association is thoroughly developed, we shall content ourselves with a couple of instances of reasoning and imagination, and with an exemplification of belief, of that kind which is most important for the full comprehension of dreams.

We not only converse, in dreams, with the persons whom we believe to be present, speaking to them, and again attributing to them connected words which we believe that they speak to us, but we frequently go so far as to make a speech or written dissertation, which, as remembered when we have awoke, is not only coherent, but often (owing to psychological circumstances peculiar to the state of sleep) more clearly and forcibly arranged than it would have been had we been awake, and had we actually spoken the speech or written the dissertation. Condillac is said to have often brought to a conclusion in his dreams reasonings on which he had been employed during the day, and which he had not completely worked out when he retired to bed. (Cabanis, 'Rapports du Physique et du Moral de l'Homme,' ii. p. 395.) Cabanis says, in the same place, of Franklin :—"I knew a very wise and enlightened man who believed he had often been instructed in his dreams concerning the issue of events which at the time occupied his mind. His strong head, and his freedom, in every other respect, from prejudice, had not been able to guard him against a superstition in respect of these inward warnings. He observed not that his profound skill and rare sagacity continued to direct the action of his brain during sleep." The circumstances under which Mr. Coleridge composed the fragment called 'Kubla Khan,' have been described by himself as the following, and we see no reason to discredit his statement. He had taken an anodyne which had been prescribed to him in consequence of a slight indisposition, and fell asleep in his chair while he was reading in 'Purchas's Pilgrimage,' of a palace built by Khan Kubla; he remained asleep for about three hours, during which, as he himself tells us, "he could not have composed less than from two to three hundred lines; if that indeed can be called composition in which all the images rose up before him as things, with a parallel production of the correspondent expressions, without any sensation or consciousness of effort." On awaking he instantly sat down to commit his poem to paper. After having written so many lines as were afterwards published, he was interrupted by a person on business; and when he returned to the task the poem had vanished from his memory.

Our belief in the presence of external objects not present is one of the most curious and, from the frequency of its occurrence, together with its curiousness, one of the most important of the phenomena of dreams. This belief is a complicated case of association. When we are awake, and, having sensations of sight from a present object, believe that the object is present, we have, first, the sensations of sight which the object excites, then the ideas of distance and extension and figure, which are closely associated with these sensations: again, the ideas of all the other sensations which the object has at other times and in other circumstances excited (those of resistance, smell, sound, &c.), and of ourselves as having these sensations: and, lastly, the idea of a cause of all those sensations, whether present or past, whether those which are themselves, or those of which only the ideas or copies are present to the mind. All those ideas, inseparably associated with the sensations of sight of which we are conscious, make up the complex state of mind called *belief in the presence of external objects*, or *belief in the existence of external objects present*. The same ideas, inseparably associated with the ideas of the sensations of sight which were themselves present in the former case, constitute another complex state, which is also a state of belief in the existence of the external objects, but which, having ideas of the sensations of sight instead of the sensations themselves, is thus distinguished from the former state, and which may be called *belief in the existence of external objects not present*. This last state of mind is the one which occurs during sleep, appearing to be the former one. Why it so appears we shall explain presently. At present we have had to do only with what it actually is, and with the associations which it comprehends.

2. It is said that a man's character and pursuits influence his dreams. Now we mean by the phrase, "a man's character," nothing more than certain classes of association which occur to him most frequently; and his "pursuits" again, viewed subjectively or in respect of himself pursuing, may be paraphrased in the same way. When we say then that a man's character and pursuits influence his dreams, it is only a way of saying that those associations which most frequently occur when he is awake will also occur most frequently, *cæteris paribus*, when he is asleep. This circumstance, therefore, observed in dreams, exemplifies the manner in which frequency strengthens association. It would be but a waste of words to bring particular instances in support of the general remark; and indeed it will be incidentally exemplified in some of the illustrations which we shall presently adduce of the influence of sensations on dreams.

3. Dreams turn upon subjects which have been present to the mind recently, rather than those which have been present to it at a greater distance of time. In other words the most recent associations will recur, *cæteris paribus*, the most frequently in our dreams. As under the last head, therefore, was exemplified the influence of frequency on association, so under the present is that of recency exemplified; and it will not be necessary to dwell any longer upon this than upon the last topic.

4. We shall enter at rather greater length into the manner in which the sensations occasionally felt in sleep modify dreams through association We have already alluded to the occasional occurrence of these sensations They are themselves very unimportant parts of dreams, even when they occur; but they call up vivid and interesting trains of ideas, the

connection between which and the sensations it is amusing to trace. We shall take the different kinds of sensations separately.

a. Of the five external senses, sight is the least excitable during sleep. But a strong light brought before the eyes of a person sleeping generally affects the nerves concerned in the sensation of sight; a sensation of a light is generally felt; and whilst its ultimate effect is almost always to awaken the sleeper, a train of ideas associated with the sensation of a light is first called up, and passes before the mind in the interval between the sensation and waking. The sleeper probably awakes from a dream of some conflagration, whether one which has actually taken place (for instance, the conflagration of Moscow, or any other which may have been impressed on his mind), or else a conflagration of some house well known to him, perhaps even his own.

b. The least excitable of the senses, after sight, is taste. And even so far as it is excitable, the circumstances under which we sleep are such as to preclude almost entirely the possibility of its being brought into action. When, however, from ill-health, or in consequence of something which we have eaten shortly before going to bed, there is (in the vulgar phrase) a bad taste in the mouth, this may have its effect on dreams.

c. Smell comes next of the senses, in respect of defect of excitability during sleep. The circumstances under which we sleep are again such as to preclude almost entirely the action of this sense; and it is difficult, while it is by no means important, to select an apposite instance of its operation in modifying dreams.

d. We come next to the sense of hearing. "The sound of a flute in the neighbourhood," says Mr. Macnish, "may invoke a thousand beautiful and delightful associations. The air is perhaps filled with the tones of harps, and all other varieties of music; nay the performers themselves are visible; and while the cause of this strange scene is one trivial instrument, he may be regaled with a rich and melodious concert" (p. 61). A loud noise taking place near the sleeper, heard by him, and eventually awaking him, calls up ideas of various loud noises, and these again various other ideas associated with them. A curious instance, which exemplifies the tendency of ideas that have been most frequently and most recently present to the mind to recur in dreams, will be found in Dr. Abercrombie's work on the Intellectual Powers, p. 277. Again, whispering in a person's ear when he is asleep is found sometimes to modify his dreams very considerably. Some persons, it is true, are instantly awaked thereby; others, who sleep on, are not conscious when they awake of having had dreams akin to the subjects on which the whisperer has discoursed; while others again may have their dreams modified at one time by the whispering, and not at another, according as the sleep is more or less deep. But instances are recorded of persons susceptible always, and, to a peculiar degree, of the influence of this whispering in the ear on their dreams; an amusing instance of which is also given by Dr. Abercrombie.

e. Of the five external senses, touch is the most excitable during sleep. In continually changing, as we do, our position during sleep, we are influenced by tactile sensations of which the bed and the bedclothes are the causes. We are most easily awaked by being touched, the slightest tickling in the nose or the sole of the foot being sufficient for the purpose. And as regards the operation of sensations of touch in modifying dreams, let it suffice to observe generally, that those by which we are awaked may call up, in the interval between the touch and the waking, ideas of various causes of touch which will be pleasurable or painful ideas according to other circumstances.

f. Sensations of bodily pain, or of disorganisation (as they have been named by Mr. Mill, who has been the first to treat of them under a separate head), including the sensations of heat and cold, frequently occur to modify dreams. Hobbes has enunciated this modifying circumstance with distinctness, interweaving however a somatological hypothesis for its explanation which is neither necessary nor correct; but this hypothesis may be kept apart from the enunciation of the fact. "And seeing dreams are caused by the distemper of some of the inward parts of the body, divers distempers must needs cause different dreams; and hence it is that lying cold breedeth dreams of fear, and raiseth the thought and image of some fearful object (*the motion from the brain to the inner parts, and from the inner parts to the brain being reciprocal*); and that as anger causeth heat in some parts of the body when we are awake; so when we sleep, the over-heating of the same parts causeth anger, and raiseth up in the brain the imagination of an enemy." ('Leviathan,' i, 2.) Several instances have been related of this by Dr. Abercrombie, Dr. Gregory, and others.

g. Sensations in the alimentary canal, sometimes pleasurable and sometimes painful, have a very important influence on dreams. These sensations indeed influence very considerably our waking trains of ideas; and much more, inasmuch as in sleep there are no external objects to call us away from the ideas which these sensations call up, do they influence our sleeping trains. When the digestion is good, and we have eaten nothing which weighs upon or disagrees with the stomach, our dreams are, generally speaking, pleasurable. When, on the other hand, we suffer from indigestion, which, in respect of the effect, is but a name for an aggregate of painful sensations in the alimentary canal, we are afflicted with dreams of the most painful character. The exhilarating effects of opium and of intoxicating draughts, which effects are neither more nor less than sensations in the alimentary canal, are also discernible in dreams. And in connection with this topic, we may allude to the dreams caused by the uneasy sensations attendant on obstructed respiration, which, sometimes caused by and sometimes combined with indigestion, constitute the most dreadful evils to which in sleep we are subject, and which are known to all under the name of nightmare.

We have thus explained the law of association which determines the formation of dreams, and have exemplified its operation. Thus far, it will be observed, we have spoken of dreams only in their generic character of trains of ideas, or at least, any reference which we have made to the specific circumstances which distinguish them from trains of ideas in the waking state has been incidental. It remains, in order to complete the psychological theory of dreams, to state and explain the circumstances distinguishing dreams, as trains of ideas during sleep, from trains of ideas as they generally occur in the waking state. We say as they generally occur, because in the waking state there are trains of ideas, which occur under peculiar circumstances, resembling dreams, and differing from the generality of trains of ideas in the waking state in those very points by means of which dreams, and the generality of waking trains, are to be distinguished from one another. The trains of ideas which in the waking state occur thus under peculiar circumstances are those called *reveries*, or, more expressively, *waking dreams*; and again, those which present themselves to the mind during delirium.

1. Ideas which occur in dreams are believed to be sensations; scenes fashioned by the fancy are believed to be real. What has been already said, when we were resolving this belief in the presence of external objects not present into its component elements, in order to exemplify the operation of the law of association in dreams, has expedited the explanation of this phenomenon. When we are awake we are conscious continually of two different states of mind, belief in the existence of external objects present, and belief in the existence of external objects not present. These two states of mind differ only in this point, that the former comprehends certain sensations of sight, while the latter, in the place of the sensations themselves, has but the ideas of the sensations. Now, when we are awake, ideas are compared with sensations, the belief in the existence of external objects not present with the belief in the existence of external objects present; and ideas are seen to be less vivid than sensations, the former belief than the latter belief. Thus, and thus alone, are these states of mind respectively distinguished from each other when we are awake; but when we are asleep we have no sensations with which to compare our ideas, and no external objects present, with the belief in whose presence we can compare the belief in their existence when they are not present. Ideas therefore, no longer viewed relatively, take the place of sensations; they are the most vivid representations which present themselves to the mind of the qualities of external objects; and being the most vivid, are believed to be sensations. Whence it follows, that the belief in the existence of external objects not present takes the place also of the belief in the existence of external objects present, or (changing the phrase) the belief in the presence of external objects. It may also be, that ideas when we are asleep are, from bodily causes which we cannot trace, actually more vivid than are the same ideas when we are awake: if this be so, which we cannot positively say, but which is probable, it will combine with the previous consideration to explain the above-mentioned phenomenon.

Dr. Hartley wrote upon this point with great sagacity; and the only fault in the following extract is the intrusion of a material hypothesis at the end of it. "The scenes which present themselves are taken to be real. Now this happens, first, because we have no other reality to oppose to the ideas which offer themselves, whereas in the common fictions of the fancy, while we are awake, there is always a set of real external objects striking some of our senses, and precluding a like mistake there, or if we become quite inattentive to external objects, the reverie does so far put on the nature of a dream as to appear a reality; secondly, the trains of visible ideas which occur in dreams are far more vivid than common visible ideas, and therefore may the more easily be taken for actual impressions. For what reasons these ideas should be so much more vivid, I cannot presume to say. I guess that the exclusion of real impressions has some share, and *the increased heat of the brain may have some likewise.* The fact is most observable in the first approaches of sleep, all the visible ideas beginning then to be more than usually glaring." ('Observations on Man,' vol. i. p. 398, ed. 1810.

Thus it is that we never dream of a past event as a past event. Any historical event of which we dream is believed to be taking place before our eyes, and any historical individual to be our companion. Another singular consequence is observable in the case of dreams produced by sensations of bodily pain. The sensation of the pain may call up, as well as kindred ideas of pain and its causes, an idea of that which will remove the pain, which, when we are awake, must often follow the sensation of pain; and this idea will be taken for the actual presence of that which is fitted to relieve us. When, for instance, we hunger or thirst in sleep, these uneasy sensations call up respectively the ideas of food or drink; we believe that we have food or drink in our possession, but (the hunger or thirst of course continuing) we go on to dream of some occurrence which prevents the satisfaction of our appetites; or perhaps we have the idea of the taste of the food or drink, and believe that we have the sensation of tasting, but yet the hunger or thirst is not allayed. Immediately some other viand or beverage presents itself to us; again are we debarred from the enjoyment, or again do we taste and profit not; and thus does the dream proceed until we awake.

The incongruity of dreams, or (in other words) the grouping of objects in our dreams which could not exist together in reality, results immediately from this mistaking of ideas for sensations. There is no more incongruity in the collocation of our ideas themselves during sleep than in that of our ideas in the waking state. In both states they follow one another according to the same law. But when we have ideas of objects during sleep, we believe that the objects are themselves present; and though the collocation of the ideas is natural, and such as would excite no surprise in the waking state, the collocation of the objects is strange, and would then also excite surprise. Dreams, though only trains of ideas, are believed at the time (as has been explained) to be successions of objects, and when afterwards remembered as such, they seem strange and incongruous. Dryden's poetical description and instance may here relieve the weariness of our own prose:—

> "Dreams are the interludes which fancy makes:
> When monarch reason sleeps, this mimic wakes,
> Compounds a medley of disjointed things,
> A court of cobblers or a mob of kings."

2. There being no sensations in sleep, as in the waking state, to break off the trains of our ideas, the associations which have been at any previous time or times formed between these ideas have more uninterrupted play when we are asleep than when we are awake. When we are awake, one idea calls up another, this perhaps a third, and thus a train of ideas is commenced, when of a sudden we see some object; the sensation then takes possession of the mind, and (in the common phrase) the attention is withdrawn from the train of ideas. When we are asleep this cannot happen; and an association between any two ideas has to give way only to a stronger association between one of them and a third.

The greater coherency, than if they were made by us when awake, of speeches or essays which we believe in our dreams that we speak or write, has been already noticed.

Thus it is that we often go through a repetition in our dreams with considerably greater ease than we can do it when awake. For the same reason, again, ideas occur to us in our dreams of which we have not for a very long time been conscious when awake, and which we have been perhaps unable, when anxious to do so, to call up; and trains of ideas are gone through, which we have, perhaps, wished to complete when awake, but to no purpose, inasmuch as the associations between the several pairs of ideas in the trains are too faint to bear up against the continual interruptions of sensations. These ideas and trains of ideas occurring in dreams, which we are unable to call up when we are awake, are said to have been forgotten.

We may observe, that the same revival of long-forgotten ideas and trains of ideas takes place often during delirium, the similarity between our trains in which state and our dreams we have already alluded to. A very singular instance of such revival during delirium is related by Mr. Coleridge, in his 'Biographia Literaria' (vol. i. chap. vi.).

To this head is to be referred a remark generally made concerning dreams, that the mind exercises no control over the ideas which compose them, or (as it is otherwise expressed) that the mind does not exert its will upon them, as it does upon ideas composing trains in the waking state. The mind is not diverted from the trains of ideas which pass before it by the occurrence of sensations; thus it need not desire, as it continually does in the waking state, to have the ideas composing the trains rather than the sensations; and thus the ideas are not presented to it, as they continually are in the waking state, in that particular combination which is called *desire of the ideas*, or *willing of the ideas*. This, we believe, is the full extent to which the remark concerning the absence of will (as it is called) over ideas in dreams is true; though, from the manner in which it is expressed, it seems, and indeed it is generally intended, to imply much more.

When we are awake, we are said to will bodily actions, and to will mental actions or ideas. Now, when we are asleep, we will bodily actions likewise; but from the manner in which the body is affected during sleep, the actions do not follow the state of mind called *will*, as they do when we are awake. We will to run from an enemy who, we believe, is pursuing us, but we cannot run; the muscles are so affected in sleep that their action does not follow the state of mind called *will*, as it does when we are awake. Every one who has dreamed must have experienced such a dream as this, and must remember the fear which follows it. But the circumstance that the action does not follow by no means affects the existence of the state of mind called *will* during dreams; and in sleep therefore, as in the waking state, we will bodily actions. Again, as regards mental actions or ideas, we exert our will over these, in the waking state, either by attending to them, or by endeavouring to recollect them, and in no other way; and every one who has dreamed must be conscious of attention to trains of ideas during his dreams, and of endeavours to recollect ideas. Thus neither as regards mental actions is there any absence during dreams of the state of mind called will.

The only difference in respect of this state of mind between dreams and waking trains is, as we have said, that in the former there is not so much need of attention to the ideas as in the latter; inasmuch as dreams are not interrupted by sensations, as are trains of ideas in the waking state.

3. Our measure of time during dreams appears not to coincide with that in the waking state. Having fallen asleep for a few moments, we believe that we go through, before we awake, a series of events which would occupy, did they really happen, days or months, or even years. And the same takes place often, when a sensation occurs to awake us, in the brief interval between the having of the sensation and the waking. Instances are not unfrequent of such dreams.

This discrepancy between our notions of time when we are asleep and when we are awake may be very easily explained. The idea of time is only an idea of so many successions of events, or of ideas, whether called up by these events or otherwise. On looking back through any period of our mental history, if we remember many feelings that have succeeded the one to the other, we have the idea of a long time; if few, of a short one. Now ideas are remembered in proportion as they are interesting or vivid. In the waking state and in sleep the same ideas would pass before the mind during the same time; but in the waking state they would be viewed as ideas only, and the greater number would not be remembered. But in sleep they are believed to be sensations, the events thought of are believed actually to take place, and the ideas thus become interesting to such a degree that they cannot be forgotten. Looking back through these ideas, and remembering every one of them, we judge the time during which they have passed before the mind to have been a long time.

4. It remains to speak of the absence of surprise in dreams. It is not indeed true that the feeling of surprise is altogether absent from dreams, as is generally asserted; while in those cases in which it is absent, and in which its absence is thought worthy of remark, the explanation is simple. In our dreams we believe that we see persons who are either dead or in a distant country, and we are not surprised; we believe that we witness events which happened a very long time ago, and we are not surprised. Now we have the ideas of the persons and events, and we have not at the same time the ideas of the death or the distant country or the distant time at which the event took place; having the ideas of the persons and events, we believe these ideas, as has been already explained, to be sensations; and as we have not, together with the apparent sensations, the ideas of the death, distant country, &c., we have no ideas with which the apparent sensations are incongruous; and there being no incongruity, there is nothing to surprise us. We think of the persons or events, as we might think of them when awake, without certain additional ideas; and not having these additional ideas, we are not surprised at seeing, or believing that we see, the persons or events, any more than we should be surprised at seeing (could we by possibility do so) the same persons or events when we were awake, if we knew not that the person had died or was in another country, or that the event was one of history.

This explanation is confirmed by those instances in which we do feel surprise. The idea of a person or event believed to be seen may call up any of the additional ideas that have before been absent. We believe that we see a person, and we then think of his death; we are immediately surprised; and we dream that we are dreaming. Every one who has dreamed must have experienced such a dream as this.

II. This second part of the article was to contain so much of the little that is known concerning the state of the body in sleep as is relevant to the subject of dreams.

The organs of the five external senses are so affected by sleep, that the sensations which respectively pertain to them are either not felt at all, or are felt very much less often, and very much less, than when we are awake, and even when they are felt they generally awake us. But of this we have already spoken.

We have also spoken of the effects of sensations of bodily pain and of internal sensations on dreams. The manner in which sickness, through the medium of internal sensations, intensifies dreams, is familiar to every one.

It is a question whether sleep operates on the mind as well as on the body; whether, while it suspends the action of the body, it also, either through the body or otherwise, suspends the action of the mind. This is a question on which we cannot speak positively, and on which our opinion can be determined only by the greater *probability* of th one side or of the other

Some writers assert that we do not always dream when we are asleep. They say that the proper effect of sleep is to suspend the action of the mind as well as of the body, and that, to the extent to which we dream, sleep is impaired. They speak of two kinds of sleep, the one in which we do not dream, and which they call *perfect* sleep; the other, in which we dream, and which they call *imperfect*. One of these writers is Mr. Locke, who has expressed a very decided opinion that during sleep we do not always think; his arguments in favour of the opinion being, that all of us are conscious of having no dreams during a considerable portion of the time that we sleep, that some persons even do not dream at all, and that a supposition that the dreams are forgotten almost the very moment after they have taken place is absurd.

('Essay on the Human Understanding,' 2, i. sec. ii.) If, however, we do not dream always, how is the beginning of our dreams accounted for? The mind is, on this supposition, at a particular period of sleep, void of ideas; an idea suddenly enters it, and dreaming begins. Now the idea was not called up by an idea antecedent to it, for antecedently there was no idea in the mind. How then did it come to enter the mind? This consideration appears to us adequate to set the question at rest as to whether we dream always or not.

Dreaming always, we may remember or forget our dreams according to whether our sleep is deep or slight, and remember them in proportion as it is not deep. One part of the same fit of sleep is more intense than another; the dreamer remembers the dreams of this last part, but forgets those of the first, as regards which it is the same as if he had not dreamt at all. In one state of health the same person has a greater amount of deep sleep than in another; he in consequence remembers his dreams better, or (as he would most probably express it) he dreams more in the second state of health than in the first. Again, one person's bodily constitution is such as to make his sleep generally more intense than that of another person, and in consequence he is less of a dreamer. There have been instances of persons who do not remember ever to have dreamed, and of others who have not remembered any dreams until at a very advanced period of life.

III. As regards the instances recorded of extraordinary dreams, they are either untrue, or true and explainable by ordinary or natural means, or else true and not so explainable, and therefore (in the common phrase) supernatural. Now many of these instances are so far authenticated, that we are not authorised altogether to discredit them. Not discrediting them, we are yet unable to explain them by the ordinary means; though it is possible, certainly, that as the dreams and their attendant circumstances come to us, there may be both some exaggeration in the dreams themselves, and some omission of incidents previous to the occurrence of the dreams which might help to explain the attendant circumstances. Again, there is another set of incidents, also well authenticated, which, like these instances of dreams, are, if we believe them as they are related, unsusceptible of explanation by ordinary or natural means. We refer to the many stories told of the appearance of persons at the moment of death, to friends or relations at a distance from the spot where the death takes place. Now these incidents pave the way to some extent for a belief in the supernatural character of some remarkable dreams. If these incidents are believed to be supernatural, there is no reason why there should not also be supernatural dreams. We must observe, however, that in calling either the incidents to which we have referred or the dreams supernatural, we mean no more than that they cannot be explained by natural means. We cannot say how they were brought about; neither can we say, looking at the particular circumstances under which they happened and the particular persons to whom they happened, why they were brought about.

The supernatural interpositions to which, in our difficulty, we resort for aid, must, if they exist, be determined by general laws, which in the course of time it either may or may not be given to men to know. At present we see only the particular interpositions, particular events belonging to another system, which we call supernatural, which is governed, however, doubtless, like our own or the natural system, by general laws, and which moves perhaps co-ordinately with this to a common end, although we know not the laws of that system, nor the connexion between it and our own. It is certainly not philosophical to refer each particular interposition to a particular providence, as is done by Bishop Bull in his sermon concerning the 'Holy Office of Angels;' but in an admission of our own ignorance, combined with an opinion that the interpositions (as they are called) are regulated by general laws, there seems to be nothing to be objected to.

Many dreams which have in former times been accounted supernatural, as revealing facts and truths of science, may doubtless be explained by means within our own knowledge. Reference has been made to Franklin's belief in revelations made to him during dreams concerning political events, but those revelations admit of a natural explanation.

There are several instances of dreams, similar to these related of himself by Franklin, given by Henry More in his 'Immortality of the Soul' (ii. 16), all of which may be explained similarly; as, for instance, the dream of Avenzoar Albumaron, an Arabian physician, to whom his lately deceased friend suggested in his sleep "a very soverain medicine for his sore eyes." Indeed all dreams of the appearance of ghosts, where they are believed to relate what may have been before known to the dreamer, may be explained by the two circumstances, that ideas in dreams are taken for sensations, and that trains of ideas associated together are not liable to be interrupted by sensations, as they are in sleep. Mr. Coleridge has very happily observed that, in the cases where ghosts are believed to appear in dreams, we have the idea of the person to whom the ghost belongs as being in the room in which we ourselves are sleeping; and further, that such ghosts always appear in a half waking state, when "the impressions of the bed, curtains, room, &c., received by the eyes in the half moments of their opening, blend with, and give vividness and appropriate distance to, the dream image, which returns when they close again." ('Literary Remains,' vol. i., p. 202.)

There is a long 'Essay on the Phenomenon of Dreaming,' in Baxter's 'Inquiry into the Nature of the Human Soul;' the object of which is to prove that dreams are brought about by the agency of spirits. However fanciful is this object, the essay is valuable, as containing many facts and displaying much ingenuity.

The theory of dreams is treated briefly in Dr. Hartley's work, in Mr. Stewart's 'Philosophy of the Human Mind' (vol. i., chap. 8), in which, however, but little is done towards the elucidation of the subject; and in Dr. Beattie's 'Dissertations.' (Lond. 1783, 4to.) Dr. Abercrombie's and Mr. Macnish's works are valuable for nothing else than the instances which they furnish. There is an article, occasioned by Mr. Macnish's book, and written by Sir William Molesworth, in the first volume of the 'London Review,' which shows great metaphysical acumen, and from which the reader will derive much instruction. A work by Dr. Brierre de Boismont, well translated and somewhat condensed by Mr. R. T. Hulme, 'On Hallucinations; a History and Explanation of Apparitions, Visions, Dreams, Ecstacy, Magnetism, and Somnambulism,' London, 1859, may also be consulted with advantage.

The works of Aristotle contain a short treatise on dreams (περὶ Ἐνυπνίων); and many valuable observations, as well as fancies, are scattered through the poem of Lucretius. There is also extant, in Greek, a work on dreams by Artemidorus, besides the 'Oneirocritikon' of Astrampsychus, and that attributed to Nicephorus, a patriarch of Constantinople.

DREDGING-MACHINES are machines employed for deepening and clearing away deposited matter from the beds of navigable rivers, canals, harbours, and basins; dredging being the term applied to such operations in common with the somewhat similar one of fishing for oysters.

Some machines employed for this purpose may be compared to ploughs, harrows, or great shovels, used only to loosen the silt or deposit, preparatory to its removal either by the action of the retiring tide or by artificial scouring or sluicing. Others not only detach the sand or silt from the bottom, but also bring it above the surface of the water and discharge it into a vessel in which it may be removed to be made use of as ballast; or, when it is not wanted for this purpose, in which it may be carried to some place where it may be emptied into deep water without doing any mischief. Boats or barges for the latter purpose are frequently made with one or more large funnel-shaped openings in the bottom, through which their contents may be discharged by simply releasing a kind of trap-door.

One of the simplest contrivances for performing this operation is that known as the spoon dredging-machine, which consists of a strong ring or hoop of wrought-iron, partially edged with steel, about two feet or rather more in diameter, attached to the end of a pole thirty or forty feet long, and carrying a large bag of bullock's hide perforated with a number of small holes. This apparatus is connected by ropes and tackle with a barge or lighter, from the side of which it is let down and manœuvred in such a manner that the steel edge of the hoop cuts into the soft bottom, and scoops a large quantity of silt into the bag, which is then drawn up to the surface. The water taken up with the silt runs through the holes in the bag, which, when sufficiently elevated, is swung over the vessel and turned so as to discharge its contents. The pole is sometimes made of two pieces, capable of sliding upon one another, to adapt the machine to various depths. By this machine, which is commonly worked by from two to four men, the quantity of stuff raised in a tide from a depth of from two and a half to three fathoms, may, with a tolerably favourable bottom, range from twenty to sixty tons.

The bucket dredging-machine is adapted for performing the operation on a much more extensive scale, and with the aid of inanimate power. It was, indeed, originally worked by men, and has been worked by the power of horses walking in a circular path in the boat, but neither of these plans is eligible, and, without the steam-engine to work it, the advantages of this form of machine are questionable. The distinguishing part of this machine is a long massive framework with a wheel at each end, over which a series of endless chains, or a band formed by two or more chains laid side by side, is placed, so that by turning one of the wheels the whole chains are set in motion. Attached to the chains is a series of iron buckets, edged with steel, and perforated with numerous small holes. This framework, with its chain of buckets, is attached by one end to supports elevated above the vessel, while the other end, which is suspended by adjustable tackle, dips obliquely into the water. In some cases the bucket-frame is mounted outside, but parallel with, the vessel to which it is attached; but another arrangement is occasionally adopted in which the hinder part of the vessel is divided by an opening in the line of the keel, sufficiently capacious to allow the working of the bucket-frame within it. By means of the tackle attached to its lower end the bucket-frame is let down until it reaches the bottom, when, the steam-engine being set to work, the chain of buckets begins to perform its circuit, by which every bucket is, in succession, made to scoop up a quantity of silt, which it carries up to the top of the oblique frame, the water running away through the holes in the bucket as it proceeds. On reaching the wheel at the upper end of the frame the bucket assumes an inverted position, and consequently pours out its contents into a barge which is brought by the side, or under the stern of the vessel, to receive them, after which it descends on the under side of the frame to be refilled. In the new edition of the 'Encyclopædia Britannica,' is a long article upon 'Dredging,' illustrated by very detailed engravings and descriptions of a large steam dredging-machine, in which the peculiarities required in the construction of steam-engines for such use are minutely explained.

DRILL. A tool used by artificers in wood, stone, or metal, for the purpose of boring holes, by means of a sharp chisel, to which a rotary motion is communicated either through a handle cranked so as to allow the power of the workman to be applied directly; or through a cord, which being moved horizontally backwards and forwards causes the vertical chisel to revolve alternately in the direction of the movement. The former class of drills having usually a moveable stock or handle, are known by the name of *stock-drills;* the drills which are driven by horizontal cords are known by the name of *bow* or *fiddle drills.* In machinery and engineering works the drills are almost always driven by the gearing of the factory. The chisel end of the drill has a sharp projecting point in the centre; and the two halves, respectively on the sides of this point, are made with their cutting edges in opposite directions.

When drills attain considerable dimensions, it is necessary to modify their forms, and they then pass into the category of boring tools.

DRILL, the course of instruction in which the soldier is taught the use of arms and the practice of military evolutions.

DRILL HUSBANDRY. [Drilling.]

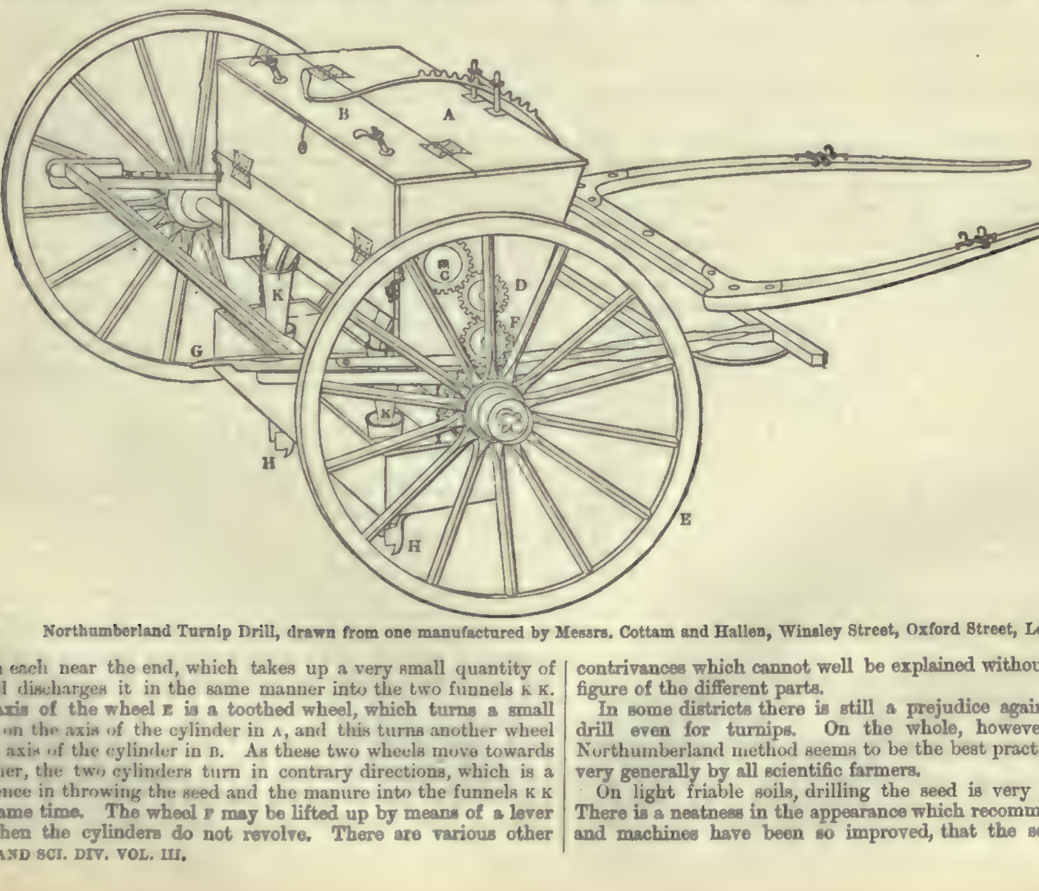
DRILLING is a mode of sowing by which the seed is deposited in regular equidistant rows, at such a depth as each kind requires for its most perfect vegetation. It has been practised by gardeners from time immemorial, and from the garden it has gradually extended to the field. In those countries where maize or Indian corn is extensively cultivated the seed is always deposited in rows; and during the growth of the plants the soil in the intervals is repeatedly hoed and stirred to a considerable depth, as is likewise the practice in vineyards. This cultivation not only keeps the land free from weeds, but by allowing the dews and the influence of the atmosphere to penetrate into the earth, greatly encourages the vegetation and growth of the plants.

It was no doubt from observing the effect produced by stirring the soil that Jethro Tull and his followers adopted the theory, that finely-divided earth formed the chief food of plants; and this led to the adoption of the row culture for every species of plant, and horse-hoeing the intervals, from which the practice obtained the name of the horse-hoeing husbandry. This was at one time thought so important a discovery as to be called the new husbandry, which was expected by its most zealous supporters entirely to supersede the old methods.

The system of Tull, as properly understood, has been long proved to have been founded on erroneous principles. But the advantage of sowing the seed in rows or drills has stood the test of experience; and the drill husbandry, by combining the advantages of continued tillage with those of manure and a judicious rotation of crops, is a decided improvement on the old methods of sowing all seeds broad-cast. The crops which are now most generally drilled are potatoes, turnips, beans, peas, beet-root, cole-seed, and carrots; and in general all plants which require room to spread, whether above or under the ground. The distance between the rows in these crops is generally such as to allow the use of a light plough or horse-hoe to be drawn by a horse between them without endangering the growing plants. The most common distance is twenty-seven inches, where the row culture is practised in its greatest perfection, which is in the north of England and in Scotland. The Northumberland mode of cultivating turnips, which is adopted by all farmers in moist climates, and seems to have decided advantages, consists in placing the manure in rows immediately under the line in which the seed is to be drilled, and keeping the intervals in a mellow and pulverised state by repeated stirring. In this mode of sowing, the seeds vegetate more rapidly, and are sooner out of danger from the fly, and the crop is more certain as well as heavier. Should the turnips fail, which with every precaution will sometimes happen, the land has had the benefit of a complete fallow, and is well prepared for any other crop.

The instrument used for sowing turnips and other seeds in single rows is sometimes a small light wheel-barrow, which a man pushes before him; hence called a drill-barrow. It has a box in which the seed is put, with a slide to regulate the quantity. This is allowed to fall on a wooden or metal cylinder below. In the circumference of this cylinder are several cavities where the seed lodges, and is carried down into a tin funnel below; the remainder is prevented from falling through by small brushes in which the cylinder turns. The motion is communicated from the wheel which runs on the ground to the cylinder by means of a chain on two pullies placed on the axes of the wheel and cylinder.

The improved Northumberland drill, of which a figure is annexed, is a more perfect as well as more complicated instrument. It is supported on two wheels, and drawn by a horse. It sows ground bones, ashes, rape-cake, or any other dry manure at the same time with the seed. The body of the drill consists of two boxes, A and B, divided by a partition between them, and each again divided into two by another partition at right-angles to the first. In the box A is put the manure, in B the seed. Iron slides are fixed in each compartment to regulate the supply of seed or manure. In the lower part of the boxes, and just before the opening, which is regulated by the slides, are two cylinders, one for the box A and another for B. On the cylinder in A are fixed shallow cups with short stems, which dip in the bones and carry a certain quantity over the cylinder as it turns, which falling in the funnels K K is deposited in the furrows made by the coulters H H. The cylinder in the box B has projecting pieces of iron, with a small cavity in each near the end, which takes up a very small quantity of seed, and discharges it in the same manner into the two funnels K K. On the axis of the wheel E is a toothed wheel, which turns a small wheel D on the axis of the cylinder in A, and this turns another wheel C on the axis of the cylinder in B. As these two wheels move towards each other, the two cylinders turn in contrary directions, which is a convenience in throwing the seed and the manure into the funnels K K at the same time. The wheel F may be lifted up by means of a lever G, and then the cylinders do not revolve. There are various other contrivances which cannot well be explained without a more detailed figure of the different parts.

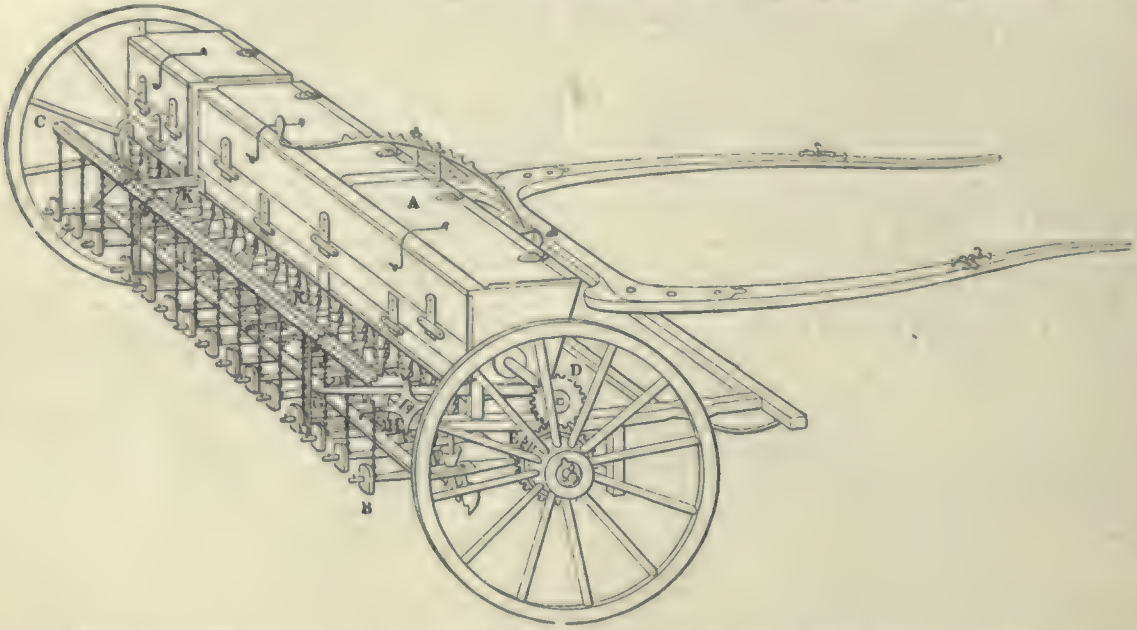


Northumberland Turnip Drill, drawn from one manufactured by Messrs. Cottam and Hallen, Winsley Street, Oxford Street, London.

In some districts there is still a prejudice against the use of the drill even for turnips. On the whole, however, drilling in the Northumberland method seems to be the best practice, and is adopted very generally by all scientific farmers.

On light friable soils, drilling the seed is very generally adopted. There is a neatness in the appearance which recommends it to the eye; and machines have been so improved, that the seed is sown more regularly and is better covered than it could possibly be by the best broad-cast sower followed by the harrows. In very stiff heavy soils, and in moist seasons, it is not so practicable to use the drill. It is sometimes impossible to get the land sufficiently dry and pulverised to allow of drilling to advantage; and when the land is wet the tread of the horses would greatly injure it. If wet clay soils were more generally underdrained, they might be rendered so dry and friable that the drill could be used at all times.

In poor sandy and gravelly soils where bones have been found of so great advantage as a manure, drilling is the only mode by which the bones and the seed can be sown in contact with each other; an important circumstance. When the ground has been well prepared and laid into stitches of a convenient width, a whole stitch may be drilled at once, with so much regularity, that an instrument with as many hoes as there are drills, and of the same width, may be drawn over the land to stir all the intervals, without danger of injuring the plants. This requires great practice and attention; but it may be considered as the perfection of the drill system. Where drilling seed is generally adopted, and the farms are not so large as to make it prudent for the occupier to purchase expensive instruments, drilling is become a separate profession. An industrious man with a small capital buys improved drills, and undertakes to drill the seed at a certain price per acre. The farmer finds horses and seed, and the driller finds the machine, and attends to the management of it himself. By constantly doing the same thing he becomes very expert; and in a neighbourhood where there are many small occupiers, a good drilling-machine, which costs from 30*l.* to 50*l.*, procures the owner a very good livelihood during the whole season of sowing: and if the instruments for hoeing were more generally used, the profession of a hoer of land might be advantageously united to that of the driller. Corn is generally drilled at the distance of eight or nine inches; and a machine which drills twelve rows will cover a stitch ten feet wide. Some prefer the rows to be nearer, but in that case the hoeing is not so easily performed with a machine, and it is done by hand. The most improved machines for drilling are made by most of our agricultural machine-makers—they are called Suffolk drills, from the county in which they originated—sowing from ten to fifteen rows at once. The description of the Northumberland turnip drill will make the construction of Cook's drill more easily understood. In the annexed figure the box for sowing manure is not added, as it is in the Northumberland drill. The drill is supported on a frame and two wheels. The box A, which holds the seed, lets it down gradually into a lower part, in which the cylinder, which has the small cups fixed to its circumference, is turned by the wheel D. By means of the lever G this may be raised so that its teeth are freed from those of the wheel E, and the motion of the cylinder is stopped. The coulters which make the drills are each fixed to a lever, at one end of which, B, a weight is fixed to press the coulter into the ground. Each coulter has a separate lever, so that it adapts itself to all the inequalities of the soil. A chain proceeds from the end of each, and may be wound round a cylinder C by turning the handles fixed to it at H, where there is also a racket-wheel to prevent its unwinding. The intent of this is to raise all the coulters out of the ground, when the drill is not intended to act, or is moved from place to place. When the drill is used, the box A is filled with seed, and the slide in it so adjusted as to supply it regularly; the lever G, which was fixed down, is raised, and the wheel D connected with the wheel E. As the horses proceed, the cylinder turns, the cups take up the seed, and throw it into the funnels K K, which conduct it to the drill behind the coulter. A light harrow, or a bush-harrow, follows, which covers the seed. In very loose soils the roller completes the operation. These figures may suffice to indicate the general form and arrangement of these machines, though there are many niceties of construction distinguishing those manufactured by different firms, which are not represented, and the description of which here is hardly consistent with the plan of this work.



Suffolk Patent Drill, drawn from one manufactured by Messrs. Cottam and Hallen, Winsley Street, Oxford Street, London.

DROITS OF ADMIRALTY are the perquisites attached to the office of Admiral of England (or Lord High Admiral), and belonging, when that office is vacant, to the crown. Of these perquisites the most valuable is the right to the property of an enemy seized on the breaking out of hostilities. Large sums were obtained by the crown on various occasions in the course of the war with France from the seizure of the enemy's property, most of which however was eventually given up to the public service. All such sums are now paid into the Exchequer, and the perquisites formerly belonging to the Lord High Admiral (a tenth) have been given by statute to the captors.

DROPSY, HYDROPS, a preternatural collection of watery fluid in different parts of the body. In the state of health, there is constantly poured out upon every surface, cavity and interstice of the body, a watery fluid derived from the blood and deposited by the capillary blood-vessels. [CAPILLARY VESSELS, NAT. HIST. DIV.] This fluid does not remain long where it is deposited, but by vessels appropriated to the office, termed absorbents, is soon taken up and reconveyed into the common circulating mass. As long as there is a perfect balance of action between these two sets of vessels, which is always the case in health, there is no accumulation of fluid, the exhalation and the absorption being always exactly equal. But if from any cause that balance be disturbed; if either the capillary blood-vessels pour out an unusual quantity of fluid, or if the absorbents fail to act with their accustomed energy, an accumulation of fluid must necessarily take place, and this accumulation, when it amounts to an appreciable quantity, constitutes the disease called dropsy. It follows that dropsy must always be the consequence either of increased exhalation or of diminished absorption.

The causes which lead to increased effusion are exceedingly various; but they are all resolvable either into those which produce a morbid condition of the blood-vessels, an obstruction to the free circulation of the blood, or a morbid condition of the blood itself. The morbid condition of the blood-vessels may be of two opposite kinds, either that of preternatural strength, in consequence of which their action may be so excited as to pour out an unusual quantity of fluid; or that of extreme debility, in consequence of which they may be unable to prevent a preternatural exudation of the thinner parts of the blood through their relaxed coats. These different states of the blood-vessels depend on two diametrically opposite conditions of the system, and accordingly the different species of dropsy are very generally divided into active or passive, acute or chronic, sthenic or asthenic.

Whenever an obstacle is opposed to the free return of the blood from the capillary arteries into the capillary veins, the blood accumulates in the capillary arteries, which are the exhalant vessels. By this accumulation of blood in the exhalents, either their action is increased, the consequence of which is increased exhalation; or their action is diminished and their tone destroyed, the consequence of which is equally increased exhalation. Various morbid conditions of many organs oppose a free return of the circulating blood from the capillary arteries into the capillary veins; any disease of the right side of the heart, for example, which prevents its receiving from the great venous trunks of the body the quantity of blood in a given time, which is necessary to maintain the balance of the circulation; any disease of the lungs, which prevents the lungs from receiving from the right ventricle of the heart the full quantity of blood which the heart has received from the great venous trunks; any disease of the liver, which prevents the liver from receiving by the great vein which ramifies through it, the vena portæ, the full quantity of blood which it ought to receive from the different abdominal viscera; any disease of the great blood-vessels themselves, by which the current of the circulating blood is prevented from passing freely through them. Such a disease of the heart may be occasioned by an ossification of its valves; of the lungs, by an obliteration or compression of its air vesicles, upon the walls of which the capillary terminations of the pulmonary artery are distributed; of the liver, by an induration of its substance and a consequent mechanical compression of the minute branches of the vena portæ; of the great blood-vessels, by diseases of their coats giving rise to the tumours called aneurisms, or by the compression of tumours existing in neighbouring parts, scirrhous, fatty, or watery tumours, which may have their seat in any organ, or by the compression of the great venous trunks of the system by the bulk of the distended uterus in pregnant women.

When dropsy is the result of an increased action of the capillary blood-vessels, it is considered a primary or idiopathic disease, and constitutes the sthenic, tonic, active, or acute dropsy of authors. In this case the capillaries are conceived to be in that state, whatever it may be, which constitute acute inflammation. The increased effusion, which constitutes the dropsy, is the result of that increased action, and by the effusion the inflamed state of the vessels is often removed.

This form of dropsy occurs most frequently in the young, the plethoric, and the robust. It is induced by all the causes of inflammation, such as cold, suddenly checked perspiration, suppression of any of the natural secretions and discharges, a plethoric condition of the system, a repulsion of acute diseases of the skin, &c. It has its seat most frequently in the serous membranes of the great cavities of the body, the walls of which are lined by those membranes, as those of the chest and abdomen, or of the viscera to which these membranes afford an external covering, as the brain, the lungs, the heart, the liver, and all the abdominal and pelvic viscera.

The third form of dropsy is that termed asthenic, or passive. It is so generally the consequence of some other morbid condition of the system that it is not usually considered a primary or idiopathic disease, but merely a sequent or ultimate result of some other pathological state. Its proximate cause is conceived to consist partly of a laxity of the tissues of the exhalant vessels, in consequence of which they are incapable of retaining the fluid part of the blood; and partly of an altered condition of the blood itself, in which its solid portions, namely, its albumen, fibrin, and red particles [BLOOD, NAT. HIST. DIV.] are preternaturally diminished, and its serum proportionally increased. The state of the system in which this form of dropsy usually comes on, and the causes which most frequently and obviously induce it, are supposed to conduce equally to this morbid state of the containing vessels and the contained blood. The state of the system in which it comes on is that of extreme debility, however induced; but its ordinary exciting causes have so obvious and great a tendency to exhaust the vital power, that they are usually denominated debilitating causes; such are fever, whether intermittent or continued, exanthematous or typhus, long continued and excessive evacuations, whether of natural discharges, or of preternatural effusions of blood, deficient or unwholesome diet, diseases of the digestive organs, by which the due assimilation of the food is prevented, intemperance in the use of intoxicating liquors, whence drunkards of all kinds, and especially dram-drinkers, so commonly, nay, almost invariably, die of dropsy.

All the acute inflammatory and febrile symptoms so characteristic of the other forms of dropsy are of course absent in this. The skin, instead of being hot, is often unusually cold; the pulse, instead of being full and hard, is weak, small, unequal, and rapid; the contraction of the heart is so feeble that slight causes often completely arrest its action, and render it incapable of carrying on the circulation, whence the patient drops down dead instantaneously, perhaps on endeavouring to walk down stairs, or to move from one chair to another; the muscles in general are flaccid, all the movements are weak, irregular, and uncertain, and all the actions of the system exceedingly feeble.

It is more especially this last form of dropsy which is induced by a morbid change in the constitution of the blood, namely, an increase in the proportion of its serum. An unusual quantity of water taken into the body, and not carried off by the excretory organs, may possibly give rise to such a condition of the blood, and accordingly it is said that suddenly drinking large draughts of very cold water has been immediately followed by dropsy, probably from the cold producing a constriction of the excretories; in consequence of which they are unable to carry off the water as it flows into the mass of blood and thus to maintain its proper constitution. A preternatural abundance of the more fluid parts of the blood may also accumulate in the circulating mass by a suppression or diminution of the ordinary aqueous excretions. Hence the influence of a cold and moist atmosphere in inducing dropsy; and the highly important influence of diseases of the kidneys in producing the disease. It is found that there are several different diseases of the kidneys of which dropsy is the ordinary result. It is the office of the kidney to remove from the blood a large proportion of its fluid parts; it is an excreting and depurating organ of the greatest importance. Any disorder of it which interferes with the performance of its function may therefore occasion an accumulation of the watery particles of the blood, and thus give rise to dropsy; and it is actually found that when the secretion of the urine is suppressed, the watery portion of the blood is often poured into some of the internal cavities. [KIDNEYS, DISEASES OF.] Moreover, large abstractions of blood are frequently followed by dropsy, because the albumen, the fibrin, and the red particles which constitute the solid parts of the blood, are not so easily renewed as the serum, and the superabundant serum readily passes off by the exhalants preternaturally relaxed by the debilitated state of the system induced by the bleeding.

The parts of the body in which the dropsical effusions usually collect are the cavities of the cranium, chest and abdomen, and the interstices of the cellular tissue diffused over the whole body, and forming a constituent element of every organ.

The dropsical fluid itself consists for the most part of the serum of the blood; but its sensible properties and its chemical constitution vary exceedingly according to the form of the disease and the condition of the capillary vessels at the moment the effusion takes place. If the vascular action have been great, the fluid is yellow or straw coloured like whey, and is more or less turbid, and contains minute particles of albumen and fibrin. If, instead of excited vascular action, the effusion have been the consequence of an altered condition of the blood, the fluid is dark-coloured and turbid, probably from the admixture of the red particles of the blood. If the effusion have taken place very slowly in consequence of the operation of some cause progressively but not rapidly impeding the circulation more and more, the fluid is almost colourless and nearly destitute of animal matter. If the fluid have been long retained in the cavity containing it, it may be of all colours and consistence, and its sensible properties may be infinitely diversified and these diversities are apparently increased by the admission of the external air to the cavity in consequence of the artificial removal of the fluid by the operation called tapping.

There are many diseases of which dropsy is the sequent, and the dropsy induced in this indirect mode is called secondary, consecutive, symptomatic, or passive, in contradistinction to its primary acute and active forms. The diseases which precede dropsy as their ordinary consequent have their principal seat in the heart, and its great vessels, in the lungs, the liver, the spleen, the kidneys, the uterus, and the ovaria. When dropsy is the consequence of disease of the heart, the signs of disease of the heart commonly long precede the appearance of the dropsy. The diseases of the heart which most commonly give rise to dropsy are passive dilatation of its muscular parietes and ossification of its valves, the existence of which may be ascertained with tolerable certainty both by certain signs which are pathognomonic of these organic changes, and by auscultation. When dropsy is the consequence of disease of the heart, the effusion is commonly indicated first by swelling of the face, especially beneath the eyelids, and next by swelling of the feet and ankles, and of the hands and arms, particularly of the left. As in the progress of the disease the effusion collects and accumulates in the cavity of the thorax, or in that of the pericardium, it is denoted by a peculiar train of symptoms. [HYDROTHORAX; HEART, DISEASES OF.] The respiration is always more or less embarrassed; the horizontal position uneasy, and often impossible; the pulse, which is seldom or never natural, is very variously affected. Whenever there is a watery swelling of the face, hands, arms, or ankles, with an impaired state of the constitution, the consequence of protracted ill health, and without manifest disease of the lungs, it may be certainly inferred that there is a disease of the heart. The dropsy which results from disease of the heart is very often completely removed by appropriate remedies. The effusion often recurs indeed, and is again removed, and this successive recurrence and removal of the affection takes place indefinitely until the cardiac disease, on which the effusion depends, reaches a point which is no longer compatible with life.

Diseases of the coats of the great blood-vessels constituting aneurism, concretions within their cavities, or tumours of neighbouring parts, pressing upon their trunks, and obstructing the passage of the blood through their canal, are frequent causes of consecutive dropsy. Inflammation of the pleura lining the cavities of the chest, inflammation and congestion of the lungs, the consolidation or hepatisation of the substance of the lungs, and the obliteration of the air-vesicles by the deposition of tuberculous matter, may give rise to effusion either into the cavity of the chest, or into the cellular tissue forming the parenchyma of the lungs, or into the cellular tissue diffused over the whole body.

Inflammation of the liver, generally of a slow or chronic nature, leading to a deposition of adventitious matter in its substance, and the consequent enlargement of the organ and the consolidation of its tissue, is a common cause of dropsy, occasioned by the obstruction to the circulation through the vena portæ, the effusion being in this case often confined to the cavity of the abdomen.

The spleen, which consists of a congeries of blood-vessels, and which is very apt to be enlarged and obstructed, may occasion effusion into the abdomen in the same manner as disease of the liver.

The kidneys are subject both to functional and organic diseases, which are followed by effusions into all the cavities, in consequence of the failure of these organs to remove from the common mass of blood the superfluous and noxious principles which it is their office to eliminate.

Dropsical effusions are often poured into the uterus and ovaria, in consequence of primary disease in these organs; at other times tumours are formed within or attached to them, which press upon and compress the trunks of neighbouring blood-vessels, and thus occasion dropsy by a mechanical obstruction to the circulation of the blood.

Dropsy is always a formidable and often a highly dangerous disease. Its acute forms, though attended with the most urgent symptoms, are in general less unfavourable than most of its chronic forms, because in the former, though the disordered actions may be very intense and dangerous, yet they are more under the control of remedial agents, and they often do not depend on any irreparable vice of the constitution, whereas the latter are the sign and the result of deep-seated and surely advancing disease. Of course the prognosis in any particular case must entirely depend on the seat and nature of the disease of which it is the sequent.

There is no disease which requires a more varied treatment than dropsy, because, like fever, dropsy may exist in, and be essentially connected with, diametrically opposite morbid conditions of the system. Dropsy may depend on a state of the system, for the removal of which all other remedies will be tried in vain unless their application be preceded by a decided abstraction of blood: dropsy may depend on a state of the system in which the abstraction of the smallest quantity of blood may prove almost instantaneously fatal; in the former case stimulants and excitants invariably increase the intensity of the disease; in the latter they are indispensable to the preservation of life. On the clear discrimination of these two different states of the system, and the two different classes of disease to which they give rise, and on the sagacious detection of the different shades by which they may appear to be blended with and lost in each other, the successful treatment of dropsy mainly depends.

(Peritonitis; Heart, Diseases of; Pleuritis; Liver, Diseases of; Ovarian Dropsy; Hydrocephalus.)

DROWNING, the state of asphyxia [Asphyxia] produced by the immersion of the body under water. When the warm-blooded animal is immersed under water, and forcibly retained there, he immediately begins to struggle violently, and uses every effort to rise to the surface. These struggles are not at first the result of pain, but of fear. It is proved by direct experiment that the obstruction to the respiration which produces pain does not come on for some time. The point of time when the painful impediment to respiration occurs is well ascertained. For the reason assigned in the article Asphyxia, in the space of three-quarters of a minute a violent effort is made to inspire, to expand the lungs with air, but no air can enter. Every effort to inspire is followed by a corresponding effort to expire. At each expiration a small quantity of air is expelled from the lungs, and is seen under the surface of the water in the form of bubbles; for although the water excludes the air from entering the lungs, notwithstanding the most violent efforts to inspire, yet it cannot prevent some portion of air from being expelled from the lungs by the violent efforts to expire. The ultimate result of these repeated and violent expirations is greatly to diminish the bulk of the lungs, and to bring them to the utmost degree of collapse to which it is possible to reduce them by any voluntary or instinctive efforts which the animal is capable of making.

When a human being is drowned by accident, if the fall has been from a considerable height and the water is not of very great depth, the body is precipitated to the bottom of the water; it then quickly rises to the surface, partly because the specific gravity of the body, when the lungs are full of air, is less than that of water, and partly because the body is rendered still lighter by the air, always amounting to a considerable quantity, which is collected and retained in the clothes. If the person be not able to swim, he generally struggles violently, and probably screams; by these efforts the lungs are partly emptied of the air they contained, the comparative weight of the body is increased, and consequently it again sinks to the bottom, but it soon again rises, and this alternate rising and sinking may occur several times in succession. Whenever the body comes to the surface and the mouth is above water, the painful impediment to respiration produces an instinctive effort to inspire, and a hurried gasp is made to obtain air. But often the mouth is not sufficiently above the surface of the water to obtain air without respiring a quantity of water along with it; but the quantity of water received in this manner is never great, probably not more than is expelled by the cough excited by the irritation of the glottis in consequence of the contact of the water and by the subsequent expiration. Every instant the body remains in the water, for the reasons immediately to be assigned, the powers of sensation and of voluntary motion rapidly diminish, and at length, perfectly insensible and motionless, it remains at the bottom of the water, where, if wholly undisturbed, it continues until the disengagement of various gases in the progress of putrefaction renders it again specifically lighter than water, and brings it once more to the surface.

The change in the system produced by continued submersion, the consequent suspension of respiration, and the necessary extinction of life, are all referrible to one pathological condition, namely, a change in the nature of the blood. The water prevents any portion of air from entering by the trachea to the air vesicles of the lungs; consequently no air comes in contact with the venous blood contained in the capillary branches of the pulmonary artery which are spread out upon the walls of these air vesicles; the venous blood which flows to the lungs is therefore incapable of being converted into arterial blood, whence the lungs can deliver to the left side of the heart only venous blood to be sent out to the system. As the circulation goes on, all the arterial blood in the body is at length converted into venous, and flows into the great venous trunks of the system, by which it is returned to the right side of the heart, and thence to the lungs, where it undergoes no change, but remains venous. These currents of venous blood, and of venous blood only, are successively sent out to the system. But venous blood is incapable of maintaining the action and vitality of the brain and spinal cord, of the heart, of the voluntary muscles, or of any organ of the body, and consequently, when nothing but venous blood circulates in the system, the death of all the organs is the sure and quick result, and the organs die in the order and mode already described. [Asphyxia.]

Taking the average of a great number of experiments, it is found that when an animal is forcibly and continuously held under water, the blood in the arteries loses its vermilion colour, and begins to grow venous in the space of three-quarters of a minute. In one minute and a quarter it is obviously dark. In one minute and a half, no difference can be distinguished between the blood in the arteries and the blood in the veins; consequently, in an animal that is submersed and that never rises to the surface, the system is brought completely under the influence of venous blood in the space of one minute and a half, and though the body should remain under water half an hour, the blood does not become sensibly darker, because it can only be completely venous.

Circumstances may make a few seconds difference in regard to the point of time when these phenomena take place. If, for example, an animal be submersed at the instant of expiration, the colour of the blood is lost somewhat sooner than when it is submersed at the instant of inspiration, and if the animal be much alarmed and struggle violently, the change takes place with greater rapidity; but the difference from any cause of this kind never amounts to more than a few seconds. Age however is capable of effecting a more remarkable difference. It is proved by numerous and accurate experiments that the younger the animal the longer it can live when deprived of air by submersion. If, as is commonly the case, an adult warm-blooded animal be irrecoverably dead in the space of four minutes after complete and continuous submersion, an animal of the same species only a few days old will live twelve minutes. A pup will live considerably longer than a young dog, a young longer than a middle aged dog, and a middle aged longer than an old dog.

Sensibility and the power of voluntary motion are diminished the moment the arterial blood begins to lose its vermilion colour; an animal is completely insensible, and has wholly lost all power of voluntary motion, that is, it is in a state of apparent death, as soon as the arterial blood is completely venous. In one minute and a half, then, after complete and continuous submersion, animal life is completely extinguished. But by the prompt and vigorous use of the appropriate remedies, recovery from this state is possible; because the organic functions go on for a considerable period after apparent death, and death is not real until the organic functions have wholly ceased. Nevertheless, though the organic functions may continue for an indefinite period after the animal functions are extinguished, from ten minutes to half an hour, or more, yet, in no instance in which the experiment has been fairly tried has any adult warm-blooded animal that has been completely and continuously submersed for the space of four minutes been capable of resuscitation, though all the means of restoring animation may have been instantaneously and most actively and judiciously employed. Accordingly it is found in practice that the immediate and vigorous use of the best means for restoring animation often fail when the person has not been in the water more than four minutes. In general, however, if the body has not been in the water longer than from five to eight minutes, the prompt and persevering use of the proper means for restoring animation will succeed; no doubt, because in some one of or in all the times that the body has come to the surface air has been obtained and conveyed to the lungs in the hurried gasp instinctively made at these moments. Still it is exceedingly rare that persons are recovered who have been in the water fifteen minutes; occasionally however animation is restored after a submersion of twenty minutes, or even half an hour; and apparently authenticated cases are on record in which resuscitation was accomplished after the body had been in the water for three-fourths of an hour. In these cases, circumstances must have favoured the occasional inspiration of air; it is utterly impossible that life can have been maintained so long unless the individual had breathed at intervals during the time; and as none can tell what circumstances may have occurred favourable to the inspiration of air, it is an imperative duty in all cases to resort to the proper means for restoring animation with all the promptitude and energy possible.

When a person who has been drowned, who was previously in a state of sound health, is taken out of the water, the appearances presented by the body are the following:—

The whole of the external surface is cold; the colour of the skin is pallid, excepting in the parts where it is livid rather than pallid, as in the face, which is always either entirely pale or slightly livid. The eyes are half open, and the pupils much dilated. The mouth and the nostrils contain a great deal of frothy fluid. A large quantity of the same kind of fluid is contained in the trachea, the bronchial tubes, and the air vesicles of the lungs. The tongue is protruded between the teeth, and approaches to the under edge of the lips. The whole head is sometimes much swollen, and the features occasionally present the appearance of those of a person who has died from apoplexy; and this is said to be particularly the case with those who have fallen into the water in a state of intoxication. It is usually considered as a sign that a person has been drowned while living, and that the body has not been thrown into the water after death, that the ends of the fingers are excoriated, and that there is a collection of dirt or sand under the nails, appearances resulting from the efforts which the drowning person has made to avert his impending fate; but if the water be deep, no appearance of this kind is present, because the power of struggling is over before the body touches the ground, and a person in the state of intoxication, who falls into deep water may expire without the power to make a single effort to save himself.

With regard to the internal organs, the heart and its great blood-vessels are always found preternaturally loaded with dark-coloured blood, sometimes to such an extent that the heart seems completely to fill the bag of the pericardium. This accumulation of black blood is always on the right side of the heart, which usually contains somewhat more than double the quantity contained in the left cavities.

The lungs are invariably very much reduced in volume, and are exceedingly loaded with black blood. Both the pulmonary arteries and veins are likewise distended with black blood.

The substance of the brain is of a darker colour than natural, and its vessels are commonly turgid with black blood; but sometimes the turgescence of the cerebral blood-vessels is not in proportion to the accumulation of blood in the other organs.

There is always a quantity of water mixed with frothy matter in the trachea and bronchi. Occasionally this frothy matter is mixed with blood. The quantity varies a good deal in different cases, but it is never very great. At one time it was thought to be so great as to be the cause of death in drowning. It was conceived that the water flows into the lungs by the trachea in such abundance as to occasion asphyxia. The controversy which was long agitated on this point is now set at rest by numerous and accurate experiments, which demonstrate that only a very inconsiderable quantity of water enters the trachea, and never sufficient to occasion death.

A similar controversy prevailed on the question whether water enters the stomach, which is now equally decided in the negative. It is proved beyond all doubt that no water passes into the stomach, or at least that no quantity enters it capable of contributing in the slightest degree to the fatal event. The establishment of this point is important, because the contrary notion had led to the adoption of most pernicious practices. With a view of evacuating the water supposed to be accumulated in the lungs and stomach, the bodies of the drowned, when taken out of the water, were held up by the heels, rolled on barrels, and subjected to other practices calculated rapidly to extinguish any remaining spark of life; and though the notion which led to these absurd practices is exploded, the practices themselves continue.

The proper remedies for the recovery of the drowned are few and simple. The body, placed on a bed-chair, should be removed to the receiving-house or any place where the conveniences required may be most easily obtained. The wet clothes should be stripped off as rapidly as possible, the body well dried and surrounded by warm air, if it can be readily procured, by the portable warm-air bath, of which there ought to be one at every receiving house. At first the heated air should only be a few degrees above the temperature of the body, and the heat, which ought always to be ascertained by a thermometer, should be subsequently increased with caution. The body being thus surrounded with warm air, artificial respiration should be performed without the delay of a moment, and this should be assisted by electricity applied at first in the form of very gentle shocks.

By the application of heat the capillary blood-vessels are stimulated to action, the determination of blood towards the external surface of the body is favoured, and the internal organs are thus relieved of their oppressive load. By artificial respiration the cavity of the chest is enlarged, the collapsed state of the lungs is removed, and atmospheric air, the great agent needed for the decarbonisation of the blood, and on the want of which all the dangerous phenomena of drowning depend, is transmitted to the lungs and brought into contact with the venalised blood. By electricity the organs which carry on the mechanical part of respiration, that is, those which alternately enlarge and diminish the capacity of the thorax, are roused and excited to resume their natural action. There are some few other useful auxiliaries, but so important and efficacious are these three powerful agents, when judiciously and perseveringly employed, that they may be considered as the only remedies worth regarding. But unfortunately they are as potent for evil as for good. A slight mismanagement of any of them may utterly destroy that life which the delicate and skilful use of it would have reanimated.

A plan of treatment of the drowned was proposed by the late Dr. Marshall Hall to the Royal Humane Society in 1856. Many instances have been recorded of the benefit of this plan, in cases of suffocation and drowning, even after the heart had entirely ceased to beat. We give this plan in Dr. Marshall Hall's own words:—

1. Treat the patient instantly on the spot, in the open air, except in the severe weather, freely exposing the face, neck, and chest to the breeze.

2. Send with all speed for medical aid, and for articles of clothing, blankets, &c.

3. Place the patient gently on the face, with one arm under the forehead, so that any fluids may flow from the throat and mouth, and without loss of time

I. *To excite Respiration.*

4. Turn the patient on his side, and
   a. Apply snuff or other irritant to the nostrils.
   b. Dash cold water on the face, previously rubbed briskly until it is warm.

If there be no success, again lose no time; but,

II. *To imitate Respiration,*

5. Replace the patient on his face (when the tongue then will fall forward, and leave the entrance into the windpipe free); then

6. Turn the body gently, but completely *on the side and a little beyond* (when *in*spiration will occur), and then on the face, making gentle pressure along the back (when *ex*piration will take place), alternately; these measures must be repeated deliberately, efficiently, and perseveringly, fifteen times in the minute *only*. Meanwhile,

III. *To induce circulation and warmth,*

continuing these measures,

7. Rub the limbs *upwards*, with firm pressure and with energy, using handkerchiefs, &c., for towels.

8. Replace the patient's wet clothing by such other covering as can be instantly procured, each bystander supplying a coat, waistcoat. &c.

"These rules," says Dr. Hall, "are founded on physiology, and whilst they comprise all that can be done immediately for the patient, exclude all apparatus, galvanism, the warm bath, &c., as useless, not to say injurious, especially the last of these, and all loss of time in removal, &c., as fatal."

DRUGS; DRUGGISTS. The difference between drugs and chemicals is vague and indeterminate; and the professions of the chemist and druggist and apothecary are in like manner generally mixed up together in popular estimation. The rules established by the medical corporations, such as the College of Physicians, the College of Surgeons, and the Apothecaries' Company, have had much to do in producing this uncertainty. The acids, alkalies, salts, and oxides used in largest quantity, are made on a scale which requires complete manufacturing arrangements, with large furnaces, stills, and other apparatus. Such is the case in relation to sulphuric and nitric acids, chlorides of lime and of sodium, alum, &c.; such articles are made by manufacturing chemists, at the vast chemical works which are met with at Glasgow, Liverpool, Newcastle, Hull, and Bristol, and to some extent in the metropolis. A retail shopkeeper who calls himself a chemist and druggist is a chemist in so far as he retails, and understands the general character of, the chemicals made on a large scale by others; while he may be regarded as a druggist to the extent that he understands, and sells by retail, the substances used in medicine. If he can himself prepare, on a small scale, a considerable number of the substances which he sells, it is now customary to term him a pharmaceutist or pharmaceutical chemist.

Dr. Normandy has published a work on drugs and chemicals, under the name of 'The Commercial Handbook of Chemical Analysis,' especially designed to afford aid in the detection of fraud in the manufacture of food, drugs, and chemicals. The list of articles of which the processes of adulteration, and the means of detection, are given, is very comprehensive; including not only ordinary viands and beverages, as bread, porter, tea, coffee, chocolate, cocoa, spirits, liqueurs, and wines, but the drugs used in medicine, and a great variety of miscellaneous substances. They are alphabetically arranged, for convenience of reference. "Country druggists," it has been remarked, "form a class of persons to whom this book would be very serviceable; for, although there are of course highly creditable exceptions, particularly in great provincial towns, the bulk of them are not distinguished for chemical or even pharmaceutical knowledge. Few are capable of conducting an analysis or organic research, and they are frequently imposed upon by wholesale dealers, who send them damaged or spurious drugs, which, if administered in dangerous maladies, might induce aggravation of disease, and very probably cause death."

A movement is being made towards placing under legislative control the sale of drugs, on the ground that frequent cases of poisoning occur through the ignorance or carelessness of retail druggists. The physicians, surgeons, and apothecaries have also endeavoured, at various times, to have the drug trade placed in some degree under professional control. Nothing, however, has yet been effected in this direction. In the "Medical Act," passed in 1858, the new General Council, formed to carry out the provisions of the Act, is empowered "to cause to be published under their direction a book containing a list of medicines and compounds, and the manner of preparing them, with the true weights and measures by which they are to be prepared and mixed, and containing such other matters and things relating thereto, as the General Council shall think fit, to be called 'British Pharmacopœia'; and the General Council shall cause to be altered, amended, and republished such Pharmacopœia as often as they shall deem necessary;" but there is a special clause, exempting chemists and druggists from any interference in the new Council, which represents all the physicians, surgeons, and apothecaries of the three kingdoms.

DRUM. [DOME.]

DRUM, a pulsatile musical instrument, of which there are three kinds,—the *Side drum*, the *base* or *Turkish drum*, and the *double drum*. The first is a cylinder or *shell*, formerly of wood, but now invariably of brass, on each end of which is a hoop covered with vellum or parchment. This is the ordinary regimental drum. The second is formed as the first, but of oak, on a much larger scale, and used, not in conjunction with the fifes, but as part of the regimental band. It is likewise employed occasionally in the orchestra. The third is made of copper, nearly hemispherical, covered with a strong *head* of calf's-skin, and stands on three iron legs. The double drums, or *kettle* drums as they are also called, vary in dimensions, from nineteen inches to three feet in diameter. They are always in pairs, and are tuned by means of many screws which tighten the head, to the key-note and the fourth below. The part for them is written in the key of C, and if the music be in another key, it is notified at the beginning as "drums in D," "drums in E♭." An improved method of tuning these instruments is by means of a lever operating on several hooks which act simultaneously on the head, or hoop on which the skin is strained, so that the tuning is performed at once, and with such rapidity, that a melody such as 'God save the Queen' can be performed on a single drum in a time not much slower than that usually adopted. A patent has been obtained by the ingenious mechanist (Mr. Cornelius Ward) to whom we are indebted for this useful invention.

About two years ago a brass drum of improved construction was introduced into the infantry regiments, weighing some three pounds less than the one previously in use, smaller in size and more portable, superior in tone and more easily tuned. This drum is manufactured by Messrs. Key, Rudall, and Co., Charing Cross, London. It is tuned by means of screws, instead of the old straps and ropes: the head which is beaten, called the *batter-head*, alone requires to be tuned, while the other head, which has three cords called the *snare*, drawn across its exterior surface, responds by reverberation. Messrs. Key and Co., have also invented a *skeleton side drum*, that is, a drum without any shell; it resembles a couple of tambourines with their concavities presented to each other; it is intended for indoor use, and gives the lightest character of tone.

DRUMMOND LIGHT. The difficulty of distinguishing the stations chosen for the angular points of the triangles in a geodetical survey, when those stations are many miles asunder, renders it necessary to have recourse to illuminations even in the day-time; and the late Captain Drummond, of the Royal Engineers, invented a heliostat which reflected the sun's rays in sufficient abundance to render the station which was to be observed visible. This was a plane mirror of a rectangular form and mounted on a stand with joints by which it could be fixed at any angle with the horizon. On the stand was a telescope which was capable of being moved horizontally, with the mirror, and directed to the distant station, while another telescope was directed to the sun. The adjustments of the mirror were such that, when the telescopes were directed, as has been said, the face of the mirror reflected the rays of the sun on the distant station, and illumined it sufficiently to render a mark there visible in the telescope of the theodolite by which the required angle was to be taken.

When it was required to observe the angles subtended between distant stations at night, the white or blue lights were first employed in this country; the materials being fixed, at the station, at times agreed upon by the parties employed in performing the operations: Argand lamps with parabolic reflectors, were used by the French, and subsequently by the English geodists; but a light which Captain Drummond obtained has been found to exceed in brilliancy any of the others. This is the *oxy-calcium* light, and is produced by placing a ball or disk of lime, about a quarter of an inch in diameter, in the focus of a parabolic mirror, at the station to be rendered visible, and directing upon it, through a flame arising from alcohol, a stream of oxygen gas. ('Philosophical Transactions,' 1826, p. 324.) The cistern containing the alcohol is supported on a stand, behind the reflector, and is connected by a tube of caoutchouc with the lower part of a hollow stem supporting the upright wire at the top of which is fixed the ball of lime on a level nearly with the cistern: the spirit ascends in the stem, and afterwards, through three or more tubes, to the ball. The vessel containing the oxygen gas is connected, by a flexible tube, with an orifice in a cylindrical box on the same stem, from whence it ascends through three flexible caoutchouc tubes to the ball, after passing with friction through three small cylinders. The whole apparatus is attached to a stand which carries the mirror; and adjustments are provided by which the ball may be placed exactly in the focus of the mirror. The intensity of the flame is from sixty to ninety times as great as that of an argand burner, while the expense is only about ten times as great. The lime made from chalk is preferred to any other; and such is the brilliancy, that stations above sixty miles from one another have been very distinctly visible even in hasy weather. In clear weather the light has been seen at a distance of 112 miles. On the 31st Dec. 1845, it was seen across the Irish Channel, at 3.30 P.M. from the top of Slieve Donard in Ireland, by an observer at the top of Snowdon, a distance of 108 miles in a direct line.

Captain Drummond suggested in a paper which was printed in the 'Philosophical Transactions' for 1830 (p. 383), that burning lime should be employed for lighthouses; and he proposed that instead of alcohol, hydrogen gas should be used with the oxygen gas. The gases were to proceed from separate vessels, or gasometers, and enter a chamber through a series of small apertures: the united gases were then to pass through two or three pieces of wire gauze, and issue in two streams against the ball or disk of lime. To prevent the latter from wasting too rapidly in one place it was made to revolve once in a minute; and in order to keep up a constant light, it was proposed to have an apparatus by which a number of balls might be successively made to fall in the focus of the mirror. The chief objection to this proposal (to say nothing of the impropriety of entrusting so explosive a compound as the mixed gases to the care of ordinary workmen) is the smallness of the flame, whereas dioptric instruments require a great body of flame for the purpose of producing a degree of divergence sufficient to render the duration of the flash in revolving lights long enough to be well made out; while in a fixed light with a reflector the same defect of volume eminently applies.

A light of this kind may also be employed as a signal in determining the difference between the longitudes of stations.

The *lime light*, as it is also called, has superseded the solar microscope, or rather can be used at all times instead of the sun; the oxy-calcium light is in great request for microscopes, phantasmagoria, and scenic effects on the stage, &c. There are some advantages in using the mixed gases contained in separate bags, since no safety jets, &c., should be relied on, but the danger in inexperienced hands is great. We have even known an accident occur in the lecture-room of an eminent chemist.

DRUSES, DOROUZ, a people who inhabit the chain of Libanus, in Syria, are under the government of their own chiefs, and have a religion peculiar to themselves. The vernacular language of the Druses is Arabic, though they have a tradition that they came originally from China. Although the mountaineers of Libanus in general obey the emir, or prince of the Druses, yet they are not all Druses, but the greater part of them are Christians of the Maronite communion, which belongs to the western, or Roman, church. [MARONITES.] Though much intermixed, they are frequently at war with each other, and such a war was being carried on in 1859. The Druses live chiefly in the south part of Libanus, east and south-east of Beiroot, and as far south as the district of Hasbeya, about the sources of the Jordan, but a few thousands are still found about Jebel-el-'Ala, in Northern Syria, where they were formerly more numerous till expelled by the Mohammedans. At Jeir el' Ashayir, a small village of Druses, there are the ruins of a large and splendid temple, a quadrangle, 90 feet by 36 feet within, on a raised platform, ornamented with Ionic columns at the angles. Towards the east the jurisdiction of the emir extends over part of the Bekaa, or plain intervening between the Libanus and the Antilibanus. North of the Bekaa is the Belad, or district of Balbek, which is inhabited chiefly by Mussulmans, and is under a distinct emir of the sect of the Metawalis, subject to the pasha of Damascus, with whom there are frequent hostilities. The former capital of the Druses was Deir el Kamr, in a valley on the west slope of Libanus, about eight or nine hours' ride south-east of *Beiroot* (Beyrut): the town is said to have about 8000 inhabitants, partly Druses and partly Christians. The town is built in the Italian fashion, and is said to resemble a second-rate country town of Italy, but it suffered greatly in the war of 1846. The land around the town displays in a marked manner the industry and skill of the inhabitants, as it is cultivated with the greatest care, and an almost barren soil made highly productive. The emir used to reside at the palace or castle of Bteddin, about one hour's ride from Deir el Kamr, which is still kept in good order, though not used for his residence. Some of the apartments of the palace are described as very handsomely furnished, paved with marble, and adorned with rich folding draperies and divans, the walls inlaid with ivory and gilding, and adorned with passages of the Koran and Scriptures in Arabic, in large embossed gilt characters, enclosed in panels of various size. The emir Beshir, as he was called, whom Captain Light saw in 1814, was described as an elderly man of an intelligent and prepossessing appearance, and said to be very regular and abstemious in his habits. He had come to the sovereignty by defeating several competitors, whom he imprisoned and put to death. (Light's 'Travels.') In 1822, having supported the rebellious Abdallah, pasha of Acre, he incurred the displeasure of the Porte, and took refuge in Egypt, but returned soon after by the mediation of Mehemet Ali, the pasha of Egypt. At the time of the occupation of Syria by Ibrahim, Mehemet's son, the Druses joined him at first; they afterwards quarrelled with him; but they were beaten, and peace was ultimately restored. Up to 1840 the emir Beshir remained faithful to the Egyptians, but as he did not separate himself before the restoration of Syria to the Turks, he was deprived of his dignity; he then withdrew, first to Malta, and afterwards to Constantinople, vainly soliciting his restoration. Kassim was named emir Beshir in his stead. The Druses and the Maronites again commenced hostilities between themselves, of which the Turks took advantage, in order to weaken their power. The civil war endured for upwards of two years, when the Porte displaced the emir el Kassim, and appointed Omar Pasha as administrator. His arbitrary conduct caused the Druses to unite with the Maronites, and both broke out into insurrection against the Turkish dominion. The Christian powers interfered, Omar Pasha was recalled, and a Turkish kaimakan appointed. This produced a partial suspension of hostilities, but the Druses still continued to acknowledge only their own chief, and in this state the country yet continues; while the Maronites sometimes have a chief of their own, and sometimes submit to the chief of the Druses. The emir has under him several subordinate emirs, or local chiefs, in various districts of the mountains, some of whom are Druses and others Maronites. As the whole population is armed and trained to the use of the gun, it is said that in case of need the emir can collect in a very short time 30,000 men; but this must be only part of the individuals capable of bearing arms, as the Maronite population alone is said to be more than 200,000, and the Druses are stated by Mr. Paton ('The Modern Syrians,' 1841), to be about 70,000.

The Druses are divided into two classes: the Akkal and the Jukhal, the initiated and the ignorant. No religious duties are imposed, but their creed includes a belief in the unity of God's five superior spiritual messengers, including Hamza and Christ; in the transmigration of souls; in the triumph of their religion; and in the renunciation of the seven points of Islamism. The Akkals make an assumption of superior morality; they neither smoke tobacco nor drink spirituous liquors; they use no bad language; and profess to abhor falsehood, but do not scruple to exercise equivocation. They meet for religious purposes every Friday evening at an hour after dusk, when they read extracts from their religious books. All the Druse women are taught to read and write. The penalty of death, it is said, would be incurred by any one who should turn Mussulman or Christian. They make no proselytes. As to the nature of their secret doctrine, we have an account of it in De Sacy's 'Chrestomathie Arabe,' vol. ii.; but how far it can be relied upon is still a question with some, as it depends upon the authenticity of the books from which De Sacy has extracted it. It is doubtful whether in fact there are any secret doctrines. It appears however pretty certain that the Druses are, or were originally, disciples of Hakem biamr Illa, the sixth Fatimite caliph of Egypt, who in the 11th century proclaimed himself to be an incarnation of the Divinity, and who established a secret lodge at Cairo, divided into nine degrees, the last of which taught the superfluousness of all religions, the indifference of human actions, &c. (Von Hammer, 'Geschichte der Assassinen,' 1818.) The Assassins themselves were a derivation of Hakem's sect, which was itself an offshoot of the great schism of the Ismaelites, a remnant of whom still exists in Syria, in the mountains east of Tortosa, near their ancient stronghold Maszyad. Hakem disappeared, probably by assassination, in one of his solitary walks near Cairo, but his disciples expect his return, when he is to reign over the world.

The Assassins, however, now called Ansayrii, are distinct from the Druses, with whom there are frequently hostile conflicts, though the emir Beshir has a nominal sovereignty over them. All agree, however, in saying that all these sects, Druses, Maronites, and Ansayrii, are industrious, brave, and hospitable: their country is a land of refuge from Turkish oppression; they pay few taxes, as the emir has lands or domains belonging to him, from which he draws his chief revenue. Silk is the staple article for exportation, by way of Beiroot. The mulberry, the vine, the fig, and other fruit-trees, are reared in the lower ridges of the Libanus, while the higher range affords good pastures. Cotton is also cultivated and manufactured. The plains, especially the Bekaa, produce corn. There are a number of convents scattered about the mountains; there is a Maronite college for the study of Syriac at Aain el Warka, and another for the Melchite students at Deir el Mhalles. Burckhardt, who crossed the Libanus in different directions, gives the names of many towns or villages inhabited by Druses and Maronites, some of them considerable places, such as Hasbeya, with 700 houses; Zahle, in the Bekaa, with 900, this is now the residence of the emir Beshir, or chief; Shirrei, near Tripoli, &c. The Druses dress differently from the Maronites: the men wear a coarse woollen beneesh, or cloak, black, with white stripes, thrown over a waistcoat, and loose breeches of the same stuff, tied round the waist by a sash of white or red linen with fringed ends; their turban is swelled out from the head into a shape resembling a turnip, and flat at the top. The women wear a coarse blue jacket and petticoat, without any stockings, and their hair plaited and hanging down in tails behind. When they dress they put on their head the Takeel, a hollow tube of silver or tin, from six to twelve inches high, shaped like a truncated cone; this cone is worn even by young female children whom Mr. Paton says he has seen adorned with it while sleeping in bed. Over this cone when the ladies are full dressed is thrown a white piece of linen, which completely envelopes the body; they also wear silver bobs tied to their tresses.

DRY PILE, a voltaic arrangement originally intended to consist of solid elements. [GALVANISM.]

DRY ROT, a term very incorrectly given to a species of decomposition and destruction of the wood used in constructive operations, arising from the fermentation of the alburnum of the sap retained in the wood (under the influence of moist warmth and confined air); and the subsequent growth of a fungoid excrescence, which destroys the cohesion of the fibres of the wood to such an extent as to reduce it to a powder. It is from the latter phenomenon that the peculiar action known as the "dry rot" takes its name, though, unquestionably, the action itself is not properly speaking a *dry* one.

It is usually considered that wood felled at those periods of the year in which the sap is rising in the trees is more exposed to this species of decay than when it has been felled later in the season; but, in fact, it would appear that the really important condition to be attained in employing any description of wood is, that a free circulation of air should be maintained around it in every direction. There have been suggested a countless number of processes for the prevention of dry rot; amongst the most successful of which may be cited Kyan's process, or the use of a solution of the bichloride of mercury; Payne's process, or the use of the sulphate and muriate of lime and the sulphate of iron in solution; Margary's process, or the use of a solution of the sulphate of copper; Burnett's process, or the use of a solution of the chloride of zinc; Boucherie's process, or the use of the pyrolignite of iron; and Bethell's process, or the use of creosote, with a small proportion of the pyrolignite of iron. It seems, nevertheless, that the results of all these processes are at the best uncertain; and it therefore behoves the builder carefully to select the soundest timber for the bearings in walls, and such other positions wherein it may be exposed to damp; and, above all things, to leave as much space as possible around the bearings, and to secure a free circulation of air about them.

There are some valuable treatises by Faraday and by Birkbeck on the subject of the prevention of dry rot, based upon the principles mentioned here.

DRYING MACHINES. A valuable improvement has been made within the last few years in the mode of drying textile fabrics which have been bleached or otherwise wetted. In the ordinary mode of drying by exposure to the open air, the moisture gradually evaporates; in a hot room this evaporation is expedited; but in the drying machine the mechanical principle of centrifugal force is applied in a singular way.

A drying machine was brought into use in Paris in 1839, by Messrs. Penzolt and Levesque. It acted on the centrifugal system. It consisted of two drums or cylinders, one within the other; the inner one being pierced with holes. The textile goods, wetted by the process of washing, scouring, or bleaching, were placed within the inner cylinder, which was then made to revolve with a rapidity of 4000 turns in a minute; the cloth was driven forcibly against the perforated surface, and the water driven through the holes with such irresistible force that the cloth became nearly dry in three or four minutes.

In 1844 Messrs Keeley and Alliott, of Nottingham, patented a very elaborate machine to facilitate the scouring, bleaching, or dyeing of cloth. The same inventors had before introduced a machine very similar in principle to that of Messrs. Penzolt and Levesque; but in the new machine, the cloth is put into a certain compartment, the bleaching or scouring liquid into another compartment, and the machine is made to revolve rapidly; the centrifugal force generated by the movement drives the liquid speedily and effectually through every pore of the cloth—leaving the cloth instantly afterwards almost in a state of dryness, and bleached likewise.

This principle, the application of centrifugal force to produce a drying action, is now very extensively adopted; the methods vary considerably in detail, but their general arrangement may be understood from the above two examples.

DUAL NUMBER. The Greek, Sanscrit, and Gothic of ancient, and the Lithuanian of modern languages, in addition to the undefined plural which they share with other tongues, possess also forms of the verb and noun in which *two* persons or things are denoted, called the dual number. On a careful consideration of the suffixes which are supposed to convey this notion, there seems reason for believing that the idea of duality was not originally contained in them, but simply that of unlimited plurality.

The suffix of plurality which belongs to the Indo-Teutonic languages seems to have had two forms, *en* and *es*, as in the English *housen* and *houses*. Thus the Greeks had two forms for the first person plural of their verbs active, *tuptomen* and *tuptomes*. In the second person, the Latin language gives the suffix *tis*, *scribitis*; probably the Greek, in its oldest character, would have presented us with a suffix *tes*, but the forms of that language which have come down to us give only the abbreviated *te*, *tuptete*. But if there existed a double form for the second person as well as for the first, we should in that case have also *tupteten*, or rather *tupteton*, seeing that to the Greek ear *ton* was a more familiar termination. In the third person the dual *ton* might well represent a plural, as the oldest form of that person in the singular gives a suffix *ti*, *esti*; and this, with the plural termination *n*, would produce a syllable which might readily take the same shape as the second person dual.

In the nouns the same analogy prevails. The nominatives and genitives of the dual and plural differ no more than might be expected in two dialects: in the dative, the difference consists in the one number having a final *n*, the other an *s*; while the accusative dual has lost the final sigma, a fate common enough with that letter in the Greek language, as may be seen even in the plural nominatives, *mousai*, *logoi*, which the analogy of the other declensions proves to have once possessed that letter. We have already seen an example of the same loss in the second person plural of the verb. Similarly in the Lithuanian from *pona* "master," we have a pl. ac. *ponùs*, dual ac. *ponù*; pl. dat. *pónāms*, dual dat. *pónām*. In the pronouns, again, the same confusion of the two numbers prevails. Thus the Greek dual of the pronoun *I* contains the very same element, *no*, which in the Latin is appropriated to the plural.

In the Gothic verb the same principle may be traced. A specimen may be seen in the second person dual which has the suffix, *ts*, a form more closely approaching the old plural suffix *tis*, which has been above mentioned, than even the *th*, which is the suffix of the same person in the plural.

Again in the Lithuanian, while the first person plural of the verb, which ends in *me*, has derived that suffix from the older form *mas*, or *mes*, the dual of the same person ends in *va*, which has a strong resemblance to our plural *we*, while the plural and dual of the second person have for suffixes respectively *te* and *ta*, both originating in an earlier *tas* or *tes*. The same observation applies to the Sanscrit verb of the Parasmaipadam form of the potential and imperative moods, and of the preterits called by Bopp "Præteritum augmentatum uniforme et multiforme." The terminations of the first persons of the dual and plural respectively in the present of the Parasmaipadam are *was* and *mas*; of the second and third persons dual respectively, *thas* and *tas*; and of the second person plural, *tha*.

If it be admitted then that the dual in its origin was not confined to the notion of two, it remains to consider how that notion was superadded. Perhaps the following may not be an unreasonable conjecture. In many countries there are two or more dialects co-existing, one among the educated and in towns, which we may call the language of books; the other, the older and more natural language of the district, not yet wholly supplanted by the former. In the places of public meeting, whether for religious or political purposes, the dialect which happens to belong to the more educated class will prevail, while the other, as genuine, though not so fortunate a dialect, will still maintain its ground by the fireside. The former will be addressed to hundreds, the latter commonly to one or two individuals. Hence the colloquial and familiar dialect of the cottage may well be borrowed by even the public speaker when speaking of two persons; and thus the notion of duality, which at first was only accidentally united with a certain suffix, becomes in the end the inseparable and essential meaning thereof. Something parallel to this may be seen in the double forms of the English verb *to be*. While *am*, *art*, *is*, are honoured by the favour of the learned, the unlearned still retain, and with as good a title, the genuine forms *be*, *best*, *bes*, or *be*. These are both indicatives, yet it is already a common practice to look upon the latter set of forms as constituting a subjunctive. Of course what has been here said does not apply to forms in which a visible representation of the idea "two" presents itself, as in the Lithuanian *tudu*, "these two," from *ta*, "this," *anudu*, "those two," from *an*, "that."

An interesting discussion by William Humboldt on the dual is printed in the 'Transactions of the Academy of Sciences of Berlin,' for the year 1827 ('Abhandlungen der historich-philologischen Klasse der Königlichen Academie der Wissenschaften zu Berlin,' aus dem Jahr 1827, p. 161–107), to which we refer our readers, though the views explained in that essay differ from those of the present article.

DUCAT, DUCATOON. [MONEY.]

DUCTILITY is that property of bodies, and more especially of certain metals, in virtue of which they can be drawn out in length, while their diameter is diminished without any actual fracture or solution of continuity; in other words, it is upon this property that the wire-drawing of metals depends. The following is given in most chemical books as the order of ductility of the metals which possess the property in the highest degree; that of the first-mentioned being the greatest: *gold*, *silver*, *platinum*, *iron*, *copper*, *zinc*, *tin*, *lead*, *nickel*, *palladium*, *cadmium*. This list would appear to require revision, and it would be very desirable to be able so to represent the ductility of the various metals numerically. In the wire trade considerable confusion exists in the gauge, that used in Birmingham for iron wire differing from that used for gold, silver, &c., while both differ from the Lancashire gauge for round steel wire. What is wanted is a scientific inquiry for the purpose of determining the order and amount of ductility of the various metals. In our best books on chemistry the statements are loose, and unsatisfactory. Thus in Gmelius, 'Handbook of Chemistry,' (Cavendish Society's Translation), it is stated (vi. 204) that *gold* is the most ductile of the metals, because it can be hammered into leaves $\frac{1}{282,000}$th of an inch in thickness, thus confounding *malleability* and *ductility*, which are different properties. It is further stated, that one grain of gold may be made to cover 56·75 square inches; or be drawn into a wire 500 feet in length. In like manner it is stated that *silver* can be beaten out into leaves 0·00001 inch in thickness; while one grain of the metal can be drawn into a wire 400 feet in length. On referring however to *platinum*, the ductility is at once ascertained, because Dr. Wollaston has furnished accurate data on the subject. Platinum alone can be drawn into a wire $\frac{1}{1200}$th of an inch in thickness, but when protected by being enclosed in a silver wire, it may be gradually reduced to $\frac{1}{30,000}$th of an inch in thickness, but in such case the wire is not coherent in long pieces.* The circumstance that silver is soluble in nitric acid, and platinum not, allows this artifice to be practised, for after having drawn the compound wire to its extreme limit, the silver can be washed off in nitric acid, leaving its central core of platinum thus considerably reduced. In the above list, a low degree of ductility is given to *palladium*, which is clearly wrong, for the latest authorities state this metal to be somewhat less ductile than platinum. Both platinum and palladium can be rolled out into thin leaves or *foil*, but their malleability is very inferior to that of gold and silver, and even copper. *Copper* and *iron* are said to be capable of being drawn out into very thin wire; sheet iron has been produced the $\frac{1}{1000}$th of an inch in thickness. Between the temperatures of 100° and 150°, *zinc* may be extended into thin plates and wires, heat being required to get rid of the crystalline texture. *Tin* cannot be drawn into fine wires, but *nickel* may be hammered either cold or hot into plates $\frac{1}{100}$th of an inch in thickness, and drawn out into wires $\frac{1}{50}$th of an inch in diameter. It is probable also, that *cadmium* is wrongly placed, since it can be easily beaten out into thin plates, or drawn into wires, whereas *tin* cannot be drawn into a fine wire. Hence it appears that although the malleability and ductility of metals are connected, they are not always in the same proportion; iron, for example, though very ductile, cannot be beaten into very thin laminæ. The difference between ductility and malleability has been ascribed to the figure and arrangement of the particles of the metals; the malleable metals may be conceived to consist of small plates, and the ductile metals of minute fibres placed beside or over each other; the one slide by their flat surfaces, the other lengthen and exert an adhesion from one extremity to the other. [WIRE-DRAWING.]

Ductility is not confined to the metals. *Glass* at a red heat possesses the property in a remarkable degree. If a rod of glass be heated at the enameller's lamp, and a portion of it drawn out and attached to a wheel, which is then to be turned rapidly, it will be encircled by a number of coils of very fine glass thread with an elliptical section, one diameter being three or four times larger than the other. The flexibility of these fibres is almost equal to those of the *spider's web*, which is also a good instance of ductility. Certain *clays* mixed with water also form a ductile mass. Hand-spun *yarns* often present threads surprisingly fine and perfect, some flax-yarns in the Great Exhibition of 1851 being what are technically known as 1200's *warp*, and 1600's *weft*.

DUELLING. The rise of the practice of duelling is to be referred to the trial by battle which obtained in early ages, jointly with the single combat or tournament of the age of chivalry, which again most probably owed its own existence to the early trial by battle. The trial by battle, or duel (as it was also called), was resorted to, in accordance with the superstitious notions of the time, as a sure means of determining the guilt or innocence of a person charged with a crime, or of adjudicating a disputed right. It was thought that God took care to see that, in every case, innocence was vindicated and justice observed. The trial by battle was introduced into England by William the Conqueror, and established in three cases; namely, in the court-martial or court of chivalry, in appeals of felony, and in civil cases upon issue joined in a writ of right. Once established as a mode of trial, the duel was retained after the superstition which had given rise to it had died away, and was resorted to for the purpose of wreaking vengeance, or gaining reputation by the display of courage. Then came the age of chivalry, with its worship of punctilio and personal prowess, its tilts and tournaments, and the duel, originally a mode of trial established by law, became in time (what it now is) a practice dependent on fashion or certain conventional rules of honour.

It is an instance of the length of time for which abused and improper obsolete laws are often allowed to encumber the English statute-book, that the trial by battle in appeals of felony and writs of right was only abolished in 1818. An appeal of felony had been brought in the previous year, in a case of murder, and the appellee had resorted to his right of demanding wager of battle (Ashford *v.* Thornton, 1 Barn. and Ald. 405). The appeal was not proceeded with, so that the barbarous encounter did not take place. [APPEAL.]

---

* In Moseley's 'Illustrations of Mechanics' (1839), the finest platinum wire is said to be $\frac{1}{3,000,000}$th of an inch in diameter, which is evidently a clerical blunder, or a printer's mistake, in putting two ciphers too many. Yet we find this mistake repeated in Dr. Golding Bird's 'Natural Philosophy' (1854), and, as if to remove all doubt in the matter, the fraction, which we have no means of measuring, is printed in words instead of figures. "The finest of these wires is but one three-millionth of an inch in diameter, and 140 of them placed together would just equal in thickness a single fibre of silk." It is remarkable that this statement is given on the high authority of Dr. Wollaston, when it will be seen, on referring to his paper contained in the 'Phil. Trans.' (1813, p. 114), that his finest platinum wire did not exceed $\frac{1}{30,000}$th of an inch in diameter.

The law of England makes no distinction between the killing of a man in a duel and other species of murder: and the seconds of both parties are also guilty of murder. But the practice of duelling has been maintained against laws human and divine; and it may be well to enter a little into the reasons of this practice, without reference to its illegality, or to its variance, which no one will dispute, with Christianity.

The professed object of a duel is *satisfaction*. The affronter professes to have satisfied the man whom he has affronted, and the challenger professes to have been satisfied by the man whom he has challenged, after they have fired, or have had an opportunity of firing, pistols at one another. That this satisfaction is of the nature of *reparation*, is of course out of the question. Satisfaction in this its most obvious sense, or reparation for an injury, cannot be effected by the injured man firing at his injurer, and being fired at in return.

The satisfaction furnished by a duel is of a different sort, and of a sort which, were it distinctly comprehended, would at once show the absurdity of the practice; it is a satisfaction occasioned by the knowledge that, by standing fire, the challenger has shown his courage, and that the world cannot call him coward. Now it is clear that there would be no reason for dissatisfaction on this point, previous to the fighting of the duel, and therefore no reason for seeking satisfaction of this sort, were it not that the practice of duelling existed. Were men not in the habit of fighting duels, and therefore not expected to expose themselves to fire after having received an affront, there would be no ground for calling their courage into question, and therefore no necessity for satisfying themselves that the world thinks them courageous. The practice of duelling thus causes the evil which it is called in to remedy,—the injury for which it is required to administer satisfaction. And every one who saw this would immediately see the absurdity of the practice. But the word *satisfaction* is conveniently ambiguous. When one speaks of it, or hears it spoken of, one thinks of that satisfaction which means reparation for an injury, and which is not the satisfaction furnished by the duel. Thus are men the dupes of words.

The real object then of the duel is, in most cases, to satisfy the person who provokes it, or who sends the challenge, that the world does not suspect him of a want of courage; and it will be useful to observe, in passing, that the duel furnishes this sort of satisfaction as well to the man who gave the affront, as to him who was affronted. Its object also, in certain cases, is doubtless to gratify the vengeance of the man who has received an affront. But in all cases the object which is professed, or generally understood to be professed, of satisfaction in the sense of reparation for the affront, is no more than a pretence.

But though the practice of duelling cannot effect the good of repairing an injury, it may very possibly effect other sorts of good. The advantage of the practice of duelling is generally said to consist in its tendency to increase courtesy and refinement of manners; as it will be a reason for a man to abstain from giving an affront, that he will be subjected in consequence to the fire of a pistol.

Now it is clear in the first place, that all the affronts which are constituted reasons or grounds of duels by fashion, or the law of honour or public opinion, are so constituted because they are judged by public opinion deserving of disapprobation. If then the practice of duelling did not exist, public opinion, which now constitutes these affronts grounds of a duel, as being deserving of disapprobation, would still condemn them, and, condemning them, provide men with a reason to abstain from them. Thus there would still exist a reason to abstain, in all cases in which the practice of duelling now provides a reason. But, in the second place, the practice of duelling itself depends on public opinion alone. A man fights because public opinion judges that he who in certain cases refuses to challenge or to accept a challenge is deserving of disapprobation: he fights from fear of public opinion. If he abstain from giving an affront on account of the existence of the practice of duelling, it is because the fear of public opinion would oblige him to fight; he abstains then from fear of public opinion. Now we have seen that there would be the fear of public opinion to deter him from the affronts which now lead to duels, if the practice of duelling did not exist. Thus the practice of duelling does not in any case provide a reason to abstain, which public opinion would not provide without its aid. As a means then of increasing courtesy and refinement of manners, the practice of duelling is unnecessary; and inasmuch as its tendency to polish manners is the only advantage which can, with any show of probability, be ascribed to it, there will be no good effects whatever to set against the evil effects which we now proceed to enumerate. There will be no difficulty in striking the balance between good and evil.

First, the practice of duelling is disadvantageous, inasmuch as it often diminishes the motives to abstain from an affront. We have seen that the existence of this practice leads public opinion to enjoy itself concerning the courage of the two persons, who (the one having affronted and the other having been affronted) are in a situation in which, according to custom or fashion, a duel takes place. Public opinion then is diverted by the practice of duelling from the affront to the extraneous consideration of the courage of the two parties. It censures the man who has given the affront only if he shrinks from a duel; and even goes so far as to censure the man who has received the affront for the same reason. Thus in a case where a man, reckless of exposing his life, is disposed to give affronts, he is certain that he can avert censure for an affront by being ready to fight a duel; and in a case where a bold or reckless man is disposed to affront one who is timid, or a man expert with the pistol one who is a bad shot, he can reckon on the man whom he affronts refusing to fight, and on censure being thus diverted from himself who has given an affront to him who has shown want of courage.

Secondly, the practice of duelling is disadvantageous, as increasing the amount of injury which one man can do to another by an affront.

Thirdly, the practice of duelling affords means for the gratification of vengeance; and thus tends to hurt the characters of individuals, by the encouragement both of that feeling, and of hypocrisy in those who, thirsting for vengeance, and daring not to own it, profess (in the common ambiguous phrase) to be seeking for satisfaction.

Fourthly (which is the most important consideration), there are the evils entailed by the deaths which the practice of duelling brings about—evils entailed both on the persons dying, and on their surviving relatives and friends. It is an evil that a man should be cut off from life "unhouseled, unappointed, unaneled." It is an evil that he should be taken from relatives and friends to whom his life is, in different ways and degrees, a source of happiness; from parents who have centred in him their hopes, and to whom, in their declining years, he might be a comfort, or from a wife and children who look to him for support.

Such are the evil effects of the practice of duelling; and there being no list of good effects to set against them, it follows immediately that the tendency of the practice is, on the whole, evil. There arises, then, the question, how is it to be got rid of?

Were a man who had killed his antagonist in a duel compelled by the law to support, or assist in supporting, some of his surviving relatives, this, so far as it would go, would be a punishment popular and efficacious. Public opinion would then infallibly be against the man who, having incurred the penalty, should endeavour to avoid it. And such a punishment as this would furthermore be superior to the punishment of death, as being susceptible of graduation—as furnishing reparation to a portion of those who have been most injured, and as preserving the offender, that he may have all those opportunities, which his natural life will afford him, of improving himself and of benefiting others.

A mild and judicious legislation would tend to guide and improve public opinion; whereas such a legislation as the present tends only to confirm it in its evil ways.

And as legislation may and should assist the formation of a right public opinion, so is it possible and desirable to operate independently on public opinion, either that the absence of good legislation may, as far as is possible, be compensated for, or that good legislation may be assisted. This operation on public opinion must be brought about by the endeavours of individuals. It is the duty of each man to oppose this practice to the utmost extent of his power, both by precept and example,—to abstain from challenging when he has received an affront, and to refuse a challenge when he is considered to have given one, making public in both cases, so far as his situation allows, his reasons for the course which he takes, and thus producing an impression against the practice as widely as he can. In the second of these two cases, he must either be able to defend, or he must apologise for, that which was considered an affront. If he can defend it, or show that the evil to the person insulted was overbalanced by the good accruing to others, he refuses rightly to be fired at for having been the author of a benefit; or, if unable to defend the affront, he apologises for it, he performs a manly and a rational part in refusing to fire at a man whose feelings he has wantonly injured.

This duty is peculiarly incumbent on public men, whose sphere of influence is larger, and whose means of producing good effects by example are therefore greater, than those of others. A public man who should at all times refuse to challenge or to accept a challenge, resting his refusal on the ground of the evil tendency of duelling, not of the infraction of some other duty which an accident has in his case connected with it (as the violation of an oath), and who should at the same time preserve himself from suspicion or reproach by circumspection in speech, by a manly defence, where it is possible, and, where it is not, by a manly apology, would be a mighty aid for the extirpation of this practice.

The following three new articles of war were issued in the course of the year 1844, with a view to the abatement of duelling in the army:—

1. Every officer who shall give or send a challenge, or who shall accept any challenge to fight a duel with another officer, or who, being privy to an intention to fight a duel, shall not take active measures to prevent such duel, or who shall upbraid another for refusing or for not giving a challenge, or who shall reject or advise the rejection, of a

reasonable proposition made for the honourable adjustment of a difference, shall be liable, if convicted before a general court-martial, to be cashiered, or suffer such other punishment as the court may award.

2. In the event of an officer being brought to a court-martial for having acted as a second in a duel, if it shall appear that such officer had strenuously exerted himself to effect an adjustment of the difference on terms consistent with the honour of both parties, and shall have failed through the unwillingness of the adverse parties to accept terms of honourable accommodation, then our will and pleasure is, that such officer shall suffer such punishment as the court may award.

3. We hereby declare our approbation of the conduct of all those who, having had the misfortune of giving offence to, or injured or insulted others, shall frankly explain, apologise, or offer redress for the same; or who, having had the misfortune of receiving offence, injury, or insult from another, shall cordially accept frank explanations, apology, or redress for the same; or who, if such explanations, apology, or redress are refused to be made or accepted, shall submit the matter to be dealt with by the commanding officer of the regiment or detachment, fort, or garrison; and we accordingly acquit of disgrace, or opinion of disadvantage, all officers and soldiers who, being willing to make or accept such redress, refuse to accept challenges, as they will only have acted as is suitable to the character of honourable men, and have done their duty as good soldiers, who subject themselves to discipline.

DUET (*Duetto*, Ital. from *Duo*), a musical composition for either two voices or two instruments. According to the Padre Martini, the *duo* is a vocal composition in the severe ecclesiastical style, without any kind of accompaniment; the *duetto*, or diminutive of *duo*, one written more freely, in a lighter manner, and admitting accompaniment. The older word is now, however, become obsolete.

DUKE, the title given to those who are in the highest rank of nobility in England. The order is not older in England than the reign of King Edward III. Previously to that reign those whom we now call the nobility consisted of the barons, a few of whom were earls. Neither baron nor earl was in those days, as now, merely a title of honour; the barons were the great tenants in chief, and the earls important officers. It does not appear that in England there was ever any office or particular trust united with the other titles of nobility, viscount, marquis, and duke. They seem to have been from the beginning merely honorary distinctions. They were introduced into England in imitation of our neighbours on the Continent. Abroad, however, the titles of duke and marquis had been used to designate persons who had political power, and even independent sovereignty. The czar was Duke of Russia or Muscovy. There were the Dukes of Saxony, Burgundy, and Aquitaine: persons with whom the earls of this country would have ranked, had they been able to maintain as much independence of the king as did the dukes on the Continent of the Germanic or Gallic confederacy.

The English word duke is from the French duc, which originally was used to signify "a man of the sword (a soldier) and of merit who led troops." The remote origin is the Latin dux, a "guide," or a "military commander." The word is used by the Latin writers to signify generally any one who has military command, but sometimes "dux," as an inferior officer, is contrasted with "imperator," commander in chief. Under the Lower Empire, dux was the title of a provincial general, who had a command in the provinces. In the time of Constantine there were thirty-five of these military commanders stationed in different parts of the empire, who were all duces or dukes, because they had military command. Ten of these dukes were also honoured with the title of comtes [COUNT], or counts. (Gibbon, 'Decline and Fall,' &c., cap. 17.)

The German word *herzog*, which corresponds to our duke, signifies "a leader of an army."

The first person created a duke in England was Edward, Prince of Wales, commonly called the Black Prince. He was created Duke of Cornwall in parliament, in 1335, the eleventh year of King Edward III. In 1350, Henry, the king's cousin, was created Duke of Lancaster, and when he died, in 1361, his daughter and heir having married John of Gaunt, the king's son, he was created Duke of Lancaster, his elder brother Lionel being made at the same time Duke of Clarence. The two younger sons of King Edward III. were not admitted to this high dignity in the reign of their father: but in the reign of Richard II., their nephew Edmund was made Duke of York, and Thomas, Duke of Gloucester.

The dignity was thus at the beginning kept within the circle of those who were by blood very nearly allied to the king, and we know not whether the creation of the great favourite of King Richard II., Robert Vere, Earl of Oxford, Duke of Ireland, and Marquis of Dublin, is to be regarded as an exception. Whether, properly speaking, an English dignity or an Irish, it had but a short endurance, the earl being so created in 1385, and attainted in 1388.

The persons who were next admitted to this high dignity were of the families of Holland and Mowbray. The former of these was half-brother to King Richard II.; and the latter was the heir of Margaret, the daughter and heir of Thomas de Brotherton, a younger son of King Edward I., which Margaret was created Duchess of Norfolk in 1358. This was the beginning of the dignity of Duke of Norfolk, which still exists, though there have been several forfeitures and temporary extinctions. Next to them, not to mention sons or brothers of the reigning king, the title was conferred on one of the Beauforts, an illegitimate son of John of Gaunt, who was created by King Henry V., Duke of Exeter. John Beaufort, another of this family, was made Duke of Somerset by King Henry VI.

In the reign of Henry VI. the title was granted more widely. There were at one time ten duchesses in his court. The families to whom the dignity was granted in this reign were the Staffords, Beauchamps, and De la Poles. In 1470, under the reign of Edward IV., George Nevil was made Duke of Bedford, but he was soon deprived of the title, and Jasper Tudor was made Duke of Bedford by his nephew King Henry VII. in the year of his accession.

King Henry VIII. created only two dukes, and both were persons nearly connected with himself; one was his own illegitimate son, whom he made Duke of Richmond, and the other was Charles Brandon, who had married the French queen, his sister, and who was made by him Duke of Suffolk. King Edward VI. created three dukes; his uncle, Edward Seymour, the Protector, Duke of Somerset (from whom the present Duke of Somerset derives his descent, and, by reversal of an attainder, his dignity), Henry Grey, Duke of Suffolk, and John Dudley, Duke of Northumberland.

Queen Elizabeth found on her accession only one duke, Thomas Howard, Duke of Norfolk, attainder or failure of male issue having extinguished the others. He was an ambitious nobleman, and aspiring to marry the Queen of Scotland, Elizabeth became jealous of him; he was convicted of treason, beheaded, and his dignity extinguished in 1572; and from that time there was no duke in the English peerage except the sons of King James I., till 1623, when Ludovick Stuart, the king's near relative, was made Duke of Richmond, which honour soon expired. In 1627, George Villiers was created Duke of Buckingham, and he and his son were the only dukes in England till the civil wars, when another of the Stuarts was made Duke of Richmond, and the king's nephew, best known by the name of Prince Rupert, Duke of Cumberland.

In the first year after the return of Charles II. from exile, he restored the Seymours to their rank of Dukes of Somerset, and created Monk, the great instrument of his return, Duke of Albemarle. In 1663, he began to introduce his illegitimate issue into the peerage under the title of duke, his son James being made in that year Duke of Monmouth. In 1664, he restored to the Howards the title of Duke of Norfolk; and in 1665 he created a Cavendish, who had held a high military command in the civil war, Duke of Newcastle. In 1682, he created the Marquis of Worcester Duke of Beaufort. As for the rest the dignity was granted only to issue of the king or to their mothers. The only duke created by King James II. was the Duke of Berwick, his natural son.

Of the families now existing, beside those who are descended from King Charles II., only the Howards, the Seymours, and the Somersets date their dukedoms from before the Revolution. The existing dukedoms originally given by Charles II. to his sons are Grafton, Richmond, and St. Albans. To the Duke of Richmond Charles granted letters patent which entitled him to a tonnage duty on coal. In 1799 this duty was commuted for an annuity of 19,000*l.* a year. The Duke of Grafton is still paid a pension of 5843*l.* a-year out of the Excise revenue, and 3407*l.* out of the Post-office revenue. The Duke of St. Albans is Hereditary Grand Falconer of England. Under King William and Queen Anne several families which had previously enjoyed the title of earls were advanced to dukedoms, as Paulet Duke of Bolton, Talbot Duke of Shrewsbury, Osborne Duke of Leeds, Russell Duke of Bedford, Cavendish Duke of Devonshire, Holles Duke of Newcastle, Churchill Duke of Marlborough, Sheffield Duke of Buckinghamshire, Manners Duke of Rutland, Montagu Duke of Montagu, Douglas Duke of Dover, Gray Duke of Kent, Hamilton Duke of Brandon; besides members of the royal family and Marshal Schomberg, who was made an English peer as Duke of Schomberg. This great accession gave an entirely new character to the dignity. King George I., besides the dukedoms in his own family, made Bertie Duke of Ancaster, Pierrepoint Duke of Kingston, Pelham Duke of Newcastle, Bentinck Duke of Portland, Wharton Duke of Wharton, Brydges Duke of Chandos, Campbell Duke of Greenwich, Montagu Duke of Manchester, Sackville Duke of Dorset, and Egerton Duke of Bridgewater. George II. created no duke out of his own family, and the only addition he can be said to have made to this branch of the peerage, was by enlarging the limitation of the Pelham dukedom of Newcastle so as to comprehend the Clintons, by whom the dukedom is now possessed. From 1720 to 1766, there was no creation of an English duke except in the royal house. In that year the representative of the ancient house of Percy was made Duke of Northumberland, and the title of Duke of Montagu, which had become extinct, was revived in the Brudenels, the heirs. The same forbearance to confer this dignity existed during the remainder of the reign; and during the reign of George IV. no dukedom was created out of the royal house, till the eminent services of the Duke of Wellington marked him out as deserving the honour of the highest rank which the king has it in his power to confer. His dukedom was created in 1814, forty-seven years after the creation of a Duke of Northumberland. The Marquis of Buckingham was advanced to the rank of Duke of Buckingham and Chandos in 1822, so that for a hundred years, namely, from 1720 to 1822, only four families were admitted to this honour.

During the reign of William IV. two dukedoms were created, Gower Duke of Sutherland, and Vane Duke of Cleveland.

The whole number of dukes in the English peerage is at present twenty, exclusive of the blood royal. There are seven Scottish dukes (Argyll, Atholl, Buccleuch, Hamilton, Lennox, Montrose, and Roxburghe), of whom one (Hamilton) is also an English duke. The only Irish duke is the Duke of Leinster.

All the dukes of England have been created by letters patent, in which the course of succession has been plainly pointed out. Generally the limitation is to the male heirs of the body.

DULCIMER, a very ancient musical instrument, and not yet entirely fallen into disuse. There seems to be little doubt of this being the psaltery, or psalterium, or nebel, of the Hebrews. In shape it was sometimes a triangle, sometimes a trapezium, as appears from Luscinius, Kircher, and Blanchinus, a fact overlooked by Sir John Hawkins, who argues in opposition to Kircher, that the instrument took different names according to its different forms. The dulcimer, as now used by street-musicians, to whom it is confined, is a trapezium in shape, has many strings, two to each note, and is struck by a pair of sticks with wooden or metallic knobs. The tone much resembles that of the old spinnet, and in skilful hands the instrument is of rather an agreeable kind. [CITOLE.]

DULCIN. [MANNITE.]

DULCOSE. [MANNITE.]

DUMASIN. A derivative chemical compound from acetone. Nothing satisfactory is known respecting it.

DUMBNESS. [DEAF AND DUMB.]

DUNES, DOWNS, and also **DENES**, are hillocks of sand formed along the sea-coast.

The word thus variously given has been usually regarded to be formed from the French *dune*, or from the Celtic *dun*, a mountain. A monastic history, repeatedly cited with respect to it, is again cited here; because it preserves two forms of this word as applied to the subjects of this article. This is the 'Compend. Chronolog. Exord. et Progress. Abbat. Clariss. B. Mariæ de *Dunis*,' by Charles de Visch, in which it is said, "Vallem reperit arenarum collibus, quos incolæ *Duynen* vocant undique cinctam."

The late learned printer, Mr. Richard Taylor, F.S.A., the editor of Tooke's 'Diversions of Purley,' in an etymological note appended to a paper by his cousin, Mr. R. Cowling Taylor, F.G.S., referred to below, says, "The appellation Denes for the sandy alluvial tracts next the sea on the Norfolk coast corresponds with *Dunes*, *Duynen*, used by the French and Flemish for those on the opposite coast. Thus Duynkerke (Dunkirk) derives its name from the church originally founded on the Denes, on the first establishment of that town."

The term *Downs* is also given, in England, to a hilly tract, or a large open plain on elevated land, whether maritime or inland, as the South Downs of the chalk of Sussex, the North Downs of that of Kent, Epsom Downs in the county of Surrey, St. Austell Downs in that of Cornwall, &c.

The mode of the formation of sand-dunes is this: the waves of the sea, in certain localities, drive upon the beach a certain quantity of fine sand, which, becoming dry during low water, is carried up still higher by the wind till, meeting with the obstruction of large stones, bushes, tufts of grass, &c., it is accumulated into little heaps; these, offering still greater surface of resistance as the sand increases upon and against them, soon rise into mounds of considerable height, whose number, arrangement, and dimensions depend naturally upon the size and distribution of the obstacles to which they owe their existence. If these obstacles are close-set, there will be little more than one range of sand hillocks, and, if very close, these will in time unite so as to form a continuous ridge. Should the arresting objects, on the contrary, be thinly scattered, and at different distances from the brink on a shelving coast, there will be several ridges of hillocks, the one behind the other. Examples of all these forms will be noticed in the sequel. The dunes having attained a certain height, the wind has no longer the power to increase their elevation, and they are then urged forward upon the land. The way in which this is effected is easily conceived. On the windward side of the hillocks the grains of sand are forced up to the top, whence they are swept off as they arrive, and fall by their own weight on the opposite slope. Thus the mass goes on invading the land, while fresh material is constantly brought by the sea.

This progress inland depends, however, upon the habitual direction of the wind and the relative direction of the coast-line. In Gascony the sand advances eastward, and generally along the whole coast of France, from Bayonne to Calais, the dunes progress in a north-easterly direction, the wind blowing most frequently from the south-west; whereas from Calais to Dunkirk, the coast trending in the direction of the wind, they make no progress inland, but form a ridge or chain parallel with the coast. The rapidity with which the sands advance is, in some cases, most alarming. Between the mouths of the Adour and the Garonne their progress is about sixty feet yearly; nor is it easy to arrest their march. The town of Mimizan is in part buried under the sands, against whose encroachment it has been struggling for the last five-and-twenty years. In Brittany, also, a village near St. Pol de Leon has been entirely covered with the sand, so as to leave no part visible but the steeple of the church.

In the Boulonnais the advance of the dunes has been almost wholly arrested since the works there executed by Cassini. The inhabitants plant a species of Cyperaceæ (the *Carex arenaria*), termed by them *oya*, which thrives well, and fixes the sands. This process is so much the more advantageous, as every hillock which becomes fixed is an effectual barrier against the invasion of fresh sand from the sea. In Gascony the peasants force the wind, in some measure, to drive back what it brought. Thus, when the wind blows in a direction contrary to that which pushes the downs upon the land, they toss the sand high into the air with shovels, and in this manner get rid of a portion of it: this portion, however is very small, and the prevailing winds being from the south-west the sands continue to advance in spite of all their efforts.

Dunes sometimes intercept the flow of water to the sea, forming stagnant pools between and behind them, which give rise to an aquatic vegetation and the occasional formation of a kind of peat.

Dunes also skirt the shores of Spain, Holland, England and Wales, and other countries, their formation being, in fact, a process which must take place to a greater or less extent on most low sandy coasts. In England, the north coast of the county of Norfolk, "between Hunstanton and Weybourne," says Sir C. Lyell ('Principles of Geology,' 9th ed. chap. xix. p. 305–307), "low hills or dunes of blown sand are formed along the shore, from 50 to 60 feet high. They are composed of dry sand, bound in a compact mass by the long creeping roots of the plant called *Marram* (*Arundo arenaria*)." He inserts a view (probably derived from the 'Geology of East Norfolk,' by the late Mr. Richard Cowling Taylor, F.G.S., which he cites) of the church of the ancient village of Eccles, half buried in the dunes, the inland slope of which is represented. At this spot they also occupy the site of houses which were still extant in the year 1605. Between it and Winterton, to the south-east, they have barred up and excluded the tide for many hundred years from the mouths of several small estuaries. Similar hills of blown sand, affording temporary protection to the coast, extend from near Happisburgh, north of Eccles, to the port of Yarmouth on the south. Mr. Taylor has also noticed the ridges of sand, another form of these accumulations, passing into dunes, provincially termed "meals" (probably from the same source with the Anglo-Saxon *mæl*, a boundary) and "meal-hills," by which the harbours of Cley, Blakeney, Wells, Burnham, and Brancaster, all on the north coast of the county, are securely defended from the fury of the northerly gales. ('Phil. Mag.,' 2nd series, vol. i. p. 427.)

As already indicated, the dunes of our eastern shores depend essentially for their formation, and also for their degree of permanence, on the remarkable disposition of the plants called *Marram*, and of the *Arundo arenaria*, or sea-reed, "in particular, to collect around them, to hold in a net-work composed of their fibres, stems, and branches, the loose and shifting sands; to bind in one comparatively compact mass, a substance which is apparently little adapted to the important office it is designed to fulfil." Other grasses and plants, however, uniting with the sea-reed to produce this effect, are on the Norfolk coast confounded with it, in popular language, under the appellation of *Marram* (probably from the Gælic *muran*, sea-reed, or perhaps from the Dutch *marren*, to bind), which is given to all of them collectively, or indifferently to any; a confusion which scientific writers on this subject have not always avoided. Among these plants the *Elymus arenarius*, or upright Sea-Lyme grass, the *Carex arenaria*, or Sea-Carex, and the *Festuca rubra*, or Creeping Fescue grass, are the most important and effective. As in France, so in Holland, and on our own eastern coast, the *Arundo arenaria* and *Carex arenaria* have been cultivated with some care on account of their utility in consolidating the sands. Acts of parliament have been passed for the preservation of *Marram*. In continuation of the view of the subject just quoted, Mr. R. C. Taylor (in 'Phil. Mag.,' as already cited, p. 296–297), has described, substantially as follows, the agency of the *A. arenaria* in this part of the process of formation of sand-hills, as examined by himself, in Norfolk, Suffolk, and Hampshire:—A small portion of the sea-reed fixes itself upon a bed of "shingle" or pebbles, with perhaps scarcely sand sufficient to cover the first root. Rapidly it sends round its creeping stolones, and these serve to arrest some portion of the sands that are constantly moved by the winds. Occasionally the quantity is sufficient for a time to overwhelm the young plant; soon it rises with increased vigour to the surface; now appearing not as one, but as many plants. Mr. Taylor once observed a single plant which had struck out stolones, ten and twelve yards in length, radiating from the original stem, their extremities thus forming a circle upwards of twenty yards in diameter. [Over and beneath which space the sand-compacting structure was thus extended.] The joints of the shoots were from six to nine inches asunder, and from each or most of these a root was directed downwards into the sand, and one or two young shoots upwards. Calculating by the number of stolones, it thus appears that this plant, during a single year, had multiplied itself five hundred-fold, independent of the further power of production by seed. Again, the sand accumulates; layer after layer succeeds; the *arenaria* spreads its shoots still further and higher, and always sends forth its creepers in search of the newly-collected sand [by the nutritive emanations of which, doubtless the vital forces of the plant on the side towards that sand are stimulated]. By its continued agency a small hillock is formed, which, by the gradual extension of the same vegetative and accumulative processes, becomes in time a ridge many feet in elevation—a "meal;" or a sand-cliff, or "dune," on which the most boisterous wave is rarely capable of encroaching. But there are limits to this resistance of the waves, which, with some related phenomena of coast-action, we must proceed to consider.

Professor Phillips, in his 'Memoirs' of his uncle, Dr. William Smith [Phillips, John, and Smith, William, in Biog. Div.], has sketched in the following comprehensive manner, the philosophy of the Norfolk sand dunes, and their relation to the changes of the coast-line.

"Along all this coast (from near Happisburgh to Winterton) the sea might enter, and spread in broad and winding sheets over 40,000 acres of land, but for a natural barrier of sand-hills, thrown up into a narrow irregular ridge by the action of the sea and the wind, and fixed by the growth of the 'marram,' or *Arundo arenaria*. The set of tide along this coast is from the N.W., and this being the line of the mud-cliffs and sand-hills, the whole of the sea-barrier thus described is raked by the currents, and the materials of which it is composed are perpetually drifted to the S.E., to augment the mass of sand-banks about Yarmouth Haven. The wasting of the cliffs to the north supplies the materials for the aggregation and renewal of the sand-hills, or dunes, and the whole coast is in motion; so long, however, as the sand-hills maintain a continuous unbroken line, they offer an effectual though variable barrier to the sea; what they have of this continuity and integrity is owing to the growth of the valuable plant already named, for its roots spread amongst and bind together the sand, and its 'bents' (stalks) check the devastating action of the wind. Placed thus in unstable equilibrium, the state of the sand-hills at any moment expresses the balance of the integral effects of the sea-wind and vegetation, and from time to time this balance is unfavourable to the safety of the inland country; for the wind often conquers the marram, by heaping up sand more abundantly where this plant grows the best; inequalities are thus occasioned; tempests succeed; the relatively depressed parts of the sandy chain yield to the wind, receive the spray, and admit unusually elevated waves of the sea. 'Gaps' or 'breaches' (fearful name!) are thus generated; the ocean, swelled by north-west winds, rushes in; the internal rivers are choked by the simultaneous flooding of the Yare with salt water; the marshes are drowned, and years pass before the soil recovers its natural state."

The manner in which Dr. Smith succeeded in conquering this fearful state of things,—as it existed in 1801, when the breaches in the line of sand-hills amounted altogether to one mile in length,—by imitating the natural embankments thrown up by the sea on the same shore, though most important as an operation of engineering, is foreign to our present subject, regarded as one of science. It is described in the Memoirs just cited, pp. 50–54.

Of the two alternating processes described by Professor Phillips, Sir C. Lyell, from his own observations and those of Mr. R. C. Taylor, has related some facts which are particular instances; of which those consisting in the restraint by the sand-dunes of the incursions of the ocean, have been already stated above; while the following show some additional consequences of the submersion of the barrier they form, and also in what manner the production of dunes is carried on in some localities of the same coast, simultaneously with the encroachment of the sea upon the land, of which other examples will be given.

The ancient villages of Shipden, Wimpwell, and Eccles (already mentioned) have disappeared; several manors and large portions of neighbouring parishes having, piece after piece, been swallowed up; nor has there been any intermission, from time immemorial, in the ravages of the sea along a line of coast twenty miles in length, in which these places stood. When Sir C. Lyell visited Eccles in 1839, the sea was fast encroaching on the sand-hills, and had laid open on the beach the foundations of a house, the upper part of which had evidently been pulled down before it had been buried under the sand. There are records of nine breaches, from 20 to 120 yards wide, having been made through the dunes between Eccles and Winterton noticed above, by which immense damage was done to the low grounds in the interior. An inland cliff, about a mile long, at Winterton, shows clearly that at that point the sea must have penetrated formerly farther than at present. But when the sufficiency of the meals and dunes securely to protect the harbours of Cley and Wells, and others, is affirmed to be dependent on "the present set of the tides,"—and is cited as "affording a clear proof that it is not the strength of the material at particular points that determines whether the sea shall be progressive or stationary, but the general contour of the coast,"—we conceive that the resisting agency of the objects and process forming the particular subjects of this article, is greatly underrated; while we are precluded from admitting the conclusion to be altogether true, even with respect to secular periods, by the fact of that secular change in the contour of coast-lines which is constantly in progress, and which Sir C. Lyell has himself evinced to play so important a part in historical physical geography.

Mr. R. C. Taylor has also described the dunes of South Wales, and some attendant phenomena ('Phil. Mag.,' 2nd series, vol. i. p. 427). The tides on this coast attain a great elevation. The marshes of Pembrey in Caermarthenshire have four or five concentric ridges of sand-hills, forming as perfect and permanent barriers against the sea as the art of man could execute. The mouth of the river Ogmore, in Glamorganshire, presented in 1827 a singular appearance of desolation, through the agency of the wind and sand. Its ancient channel was filled up for two miles, houses were rendered uninhabitable, and sand-hills were raised to the height of nearly 150 feet. "The mountains which bound the harbour," Mr. Taylor observed at that time, "will check the advance of this sand-flood into the interior, otherwise it threatens to overwhelm all the lands which adjoin it; while the squalls of wind, rushing down the steep valleys, occasion eddies, which deposit the sand at an elevation apparently far beyond the reach of such an irresistible enemy."

Much information respecting the sand-dunes of Cornwall, their encroachment on the land, and its counteraction by the use of the *Arundo arenaria*, will be found in the 'Parochial History' of that county by the late Mr. Davies Gilbert, P.R.S., and in the late Messrs. Lysons's 'Magna Britannia.'

"M. Elie de Beaumont [in his 'Géologie Pratique,' p. 218] has suggested that sand-dunes in Holland and other countries may serve as natural chronometers, by which the date of the existing continents may be ascertained. The sands, he says, are continually blown inland by the force of the winds, and by observing the rate of their march we may calculate the period when the movement commenced." On this, Sir C. Lyell, whose 'Principles' we are again citing, observes "But the example just given [that of Eccles] will satisfy every geologist that we cannot ascertain the starting point of dunes, all coasts being liable to waste, and the shores of the Low Countries in particular being not only exposed to inroads of the sea, but, as M. de Beaumont himself has well shown, having, even in historical times undergone a change of level. The dunes may indeed, in some cases, be made use of as chronometers, to enable us to assign a minimum of antiquity to existing coast-lines; but this test must be applied with great caution, so variable is the rate at which sands may advance into the interior."

Dr. Boué has pointed to sandy sea-beaches as being the only formations now in progress, which are similar to deserts. [Deserts.] If the latter have been produced by the gradual extension of the former, we may probably conclude that the permanent accumulation of sand was effected by the continual successive formation of dunes. In all past ages of the earth's physical history, as at the present era, they must have been formed wherever there was sea, together with rocks, the disintegration of which would afford the requisite material, if the form of coast-line, and the nature of its vegetable productions, and the prevalent direction of the winds were also favourable. And accordingly, sandstones of almost every geological age might be referred to containing vestiges of organic matter, lineally disposed, which may have resulted from their consolidation. These are more evident, however, in the later secondary and in the tertiary strata than in sandstones of great comparative antiquity; as might naturally be expected, from the longer exposure of the latter to metamorphic action, and the gradual obliteration of organic impressions by the various processes of alteration in rocks, the operation of which is permitted by the lapse of time.

DUNG. [Manure.]

DUODECIMALS, a term applied to an arithmetical method of ascertaining the number of square feet and square inches in a rectangular space whose sides are given in feet and inches. For instance, to find the contents of 6 feet 7 inches by 2 feet 5 inches, proceed as follows:

Feet.	Inches.	
6	7	
2	5	
13	2	
2	8	11
15	10	11

In the answer, 15 means 15 square feet; 10 means 10 strips of one foot by one inch, or 10-twelfths of a square foot; 11 means 11 square inches, or 11-144ths of a square foot. This result is obtained as follows:—

2 feet by 6 feet gives	12 square feet.
2 feet by 7 inches gives or 14-12ths of a square foot.	1 ,, foot, 2-twelfths,
	13 square feet, 2-twelfths.
6 feet by 5 inches gives or 30-12ths of a square foot.	2 square feet, 6-twelfths,
7 inches by 5 inches gives or 35 square inches.	2-12ths, 11 sq. in.
	2 square feet, 8-12ths. 11 sq. in.

The following instances are perfectly similar:

Feet.	Inches.		Feet.	Inches.
11	10		3	4
12	7		8	6
142	0		26	8
6	10	10	1	8
148	10	10	28	4

DUPLEX QUERE'LA (double querele or complaint), a process in ecclesiastical causes, in the nature of an appeal from the ordinary to his next immediate superior, as from a bishop to an archbishop, or from the archbishop to the crown in council. It seems to have been called double querele, because in its form it is a complaint both against the judge and against the party at whose suit justice is delayed. (Blackst. 'Comm.,' Mr. Kerr's edit., iii. 256.)

DUPLICATE RATIO (λόγος διπλασίων), a term used by Euclid, and defined as follows: If A be to B in the same proportion as B to C, then the ratio of A to C is called the duplicate ratio of A to B. When A, B, and C are lines, the duplicate ratio of A to B is that of the square on A to the square on B; when numbers, that of A times A to B times B. [Ratio; Exponent.]

DUPLICATION OF THE CUBE, the solution of the following problem: to find the side of a cube which shall be double that of another cube. This question, which is insoluble with perfect exactness by the methods of ordinary geometry, attained such a degree of notoriety among the Greek geometers that its origin was the subject of a mythologic fable. Eutocius, in his commentary on the sphere and cylinder of Archimedes, has preserved a letter of Eratosthenes to Ptolemy (Euergetes) in which it is said that one of the tragedians (Euripides, according to Valckenaer, cited by Montucla's editor) had introduced Minos erecting a sepulchre to Glaucus. The architect proposed one hundred palms every way, on which Minos declared that such a size would be too small for a royal sepulchre, and required that it should be doubled in size; and thereupon arose the difficulty. Eratosthenes also states another fable, namely, that the Delians, during a pestilence, had been ordered by the oracle to produce a cubical altar double of one which then existed. They applied to the school of Plato at Athens, who found that the problem eluded all their efforts. Other writers make mention of the latter story, and Valerius Maximus, in particular, adds that Plato referred the querists to Euclid; which must be an anachronism. However this may be, the problem continued to furnish an unceasing object of research; and such was the importance of its solution in the eyes of Eratosthenes, that he hung up his own solution in a temple as an offering, and composed an epigram, of which the principal value now is the proof which it affords that he considered Menæchmus as the first inventor of the conic sections.

Hippocrates of Chios, known as the first who could find the area of a (not *any*) curvilinear figure, perceived, according to Eratosthenes, that this problem could be solved as soon as two mean proportionals could be found between the side of the given cube and twice its length; that is, A being the length of the given cube, and X and Y two lines such that

$$A : X :: X : Y \text{ and } X : Y :: Y : 2A,$$

this geometer saw that X was the side of the cube double of that on A. But the new problem presented exactly the same difficulty as before; various mechanical curves (as they were called) were invented for the purpose; it was found that the conic sections were sufficient, but no solution appeared consistent with the restrictions implied in the postulates of Euclid.

Eutocius has mentioned the solution of Eudoxus, and has preserved those of Plato, Hero, Philo, Apollonius, Diocles, Pappus, Sporus, Menæchmus, Archytas, Eratosthenes, and Nicomedes. Pappus himself (in the third book, the first of those which remain entire) has preserved the solutions of Eratosthenes, Nicomedes, and Hero. In several instances these notices are the only clue which we have to the dates of the investigators, as there is strong presumption that those who are named by Eutocius and not by Pappus lived between the two.

The trisection of the angle [Trisection] offered difficulties of a similar kind, and engaged the attention of several of the individuals above mentioned. That of the quadrature of the circle is altogether of another kind. For the various solutions of the problem of the duplication, see Montucla, 'Histoire des Recherches sur la Quadrature du Cercle,' 2nd edition, Paris, 1831; or Reimer, 'Historia Problematis de Cubi Duplicatione,' Göttingen, 1798; or the works of Eutocius and Pappus already cited.

The importance of this problem declined with the rise of the decimal arithmetic. Many different attempts were made, some avowedly mechanical (as opposed to geometrical), others by those who imagined they could overcome the original difficulty. Any process for the solution was called *mesolabum* (a term as old as Vitruvius). One of the last was that of the celebrated Vieta, containing an error, which is the more remarkable, that little, if any, notice has ever been taken of it. (See his works, Schooten's edition, p. 273.)

DUST, ATMOSPHERIC; DUST-HAZE; DUST-STORM; are terms designating related phenomena, depending on the suspension in the air of congeries of solid particles, which, within about a quarter of a century past have received some definite scientific attention; finely-divided solid matter, derived from the mineral kingdom, together with minute organisms or fragments of animal and vegetable origin, having come to be regarded as forming a proximate element of the lower strata of the atmosphere, regarded in the gross. Their suspension, no doubt, is dependent on the principle of the internal friction of the air, to which Professor Stokes has referred that of the clouds. [Cloud.]

The great pioneer of systematic and scientific micrology, Professor Ehrenberg of Berlin, who has done for a host of the objects of natural history requiring the microscope for their investigation, or even distinct vision, nearly what Linnæus did for all the species of organic nature known to him, which could be examined by the unassisted, or but slightly assisted, eye, has not omitted to extend his philosophic scrutiny and distribution to the motes that float in the air, referring them to their places in nature, or to the creatures from which they have been derived. In 1849, he published collectively the results of the researches on this subject which he had then been pursuing for some years, under the title of 'Dust of the Regular-Winds and Blood-rains,' &c., consisting of 192 folio pages, and containing seven tabular catalogues, and six coloured plates of particles of atmospheric dust as viewed by the microscope. A synopsis of the contents of this work will be found in the 'Pharmaceutical Journal,' edited by the late Jacob Bell, for June 1850, vol. ix., pp. 569–575. From this it appears that the dust of the regular winds yields to chemical examination—silica, alumina, potash, soda, oxide of iron, oxide of manganese, oxide of copper, carbonate of lime, magnesia, water, and organic (combustible) bodies. By microscopic analysis are discerned in it fine quartz sand, still finer yellowish or reddish mould (very fine granular dust, *Gallionella ferruginea ?*), mixed with numerous organic forms and fragments. Generally single isolated fragments of pumice are observed in it, but chiefly green prismatic crystals, as in volcanic tufa and *rapilli*. Likewise white calcareous crystals which readily dissolve in muriatic acid. The organic substances are *Polygastrica*, *Phytolitharia*, *Polythalamia*, and soft vegetable parts. The total number of organic forms observed at this period amounted to 320 species; but many more have since been discovered, and have been described in Professor Ehrenberg's communications to the Royal Academy of Sciences at Berlin, continuing the elaborate investigation of which we here present merely a few results.

Over the island of Teneriffe, as recorded in Professor C. Piazzi Smyth's Report on the astronomical experiment in that locality, in the year 1856—the principal object of which was to ascertain, by following out a suggestion of Newton, how much celestial observation can be benefited by eliminating the lower third or fourth parts of the atmosphere—the existence of atmospheric dust is manifested in a remarkble manner, affecting all the phenomena dependent on the transparency and the transcalescence of the air. When describing the astronomical qualities of the atmosphere at his observing stations on the Peak, and after noticing those arising from the winds and the clouds, he thus describes those which are imparted by the dust: "A more important quality of the atmosphere was caused by the dust-haze, which was ever more or less present, though sometimes in vastly greater quantities than at others, and was precisely that which injured, or rendered impossible, daylight observations of stars (weakening direct light and multiplying general light). Where this dust-haze came from or went we could never tell; but, when present, we could easily distinguish its banks, or strata—dense strata, far above the clouds of the north-east trade-wind—as they stretched away and condensed in perspective towards the horizon. There were often several strata, one above the other, and mutually separated by very clear and sharply-defined spaces of atmosphere. When, as was sometimes the case, the summits of Grand Canary, or of Palma [other islands of the group], rising high above the sea of clouds, pierced also these upper strata of dust-haze, we had from [the observing station of] Guajara, the curious phenomenon of zones of blue mountain alternately distinct and again indistinct almost to invisibility, and yet no cloud or other recognised impurity of the atmosphere intervened. Being above much of this dust, though perhaps not the greater part of it [the elevation of the station being 8903 feet, and the dust-strata rising to not less than 11,000 feet], we were evidently better off than an observer at the level of the sea, when pointing to a zenith object, but for a horizontal one we were worse off, from often being *in*, and then looking *through* the whole plane of the stratum, and so experiencing the maximum of its light-stopping effect. Hence the occasional deterioration of sunrise and sunset were infinitely greater than anything that occurred at noon; and on some days, when the sky was perfectly free from cloud, and the sun had been distressingly hot and bright when high in the sky, yet it had almost become invisible before it set. It was seen, though made out with difficulty on such occasions, through a darkling, yet luminous haze of dull lemon-yellow colour; but what it set behind, or when exactly it did set, there was no ascertaining. The next evening perhaps the atmospheric dust had removed, and the change in the sunset was magical. The orb radiated hot and bright up to the moment of going down. Then, too, in place of the uniform yellow colour of the dusty sunset, the most gorgeous scarlets, yellows, and blues took its place."

From his experiments on the radiation of the sun, Professor Smyth says on this subject, after drawing some important inferences, "Towards the chief astronomical end of the expedition, there is a yet more interesting conclusion to be drawn. The days of highest radiation are those of least temperature, and *vice versâ*: and this difference obtains in a signal degree when there was no visible disturbing action of wind or clouds. What then causes the radiation of one day to be greater than that of another, and the temperature less? The immediate agent appears to be the atmospheric dust," diminishing by its interposition the effect of the solar radiation, but at the same time augmenting the temperature of the air by the multiplied radiation and reflection from its particles, in a manner corresponding to its action upon light as already noticed. "Hence then, we may easily understand why the small difference of altitude [1800 feet] between Alta

Vista [the upper observing station], and Guajara produced as great an increase in the radiation as did the great difference, nearly four times as great, between Guajara" itself, and the town of Oratava at the base of the mountain.

"To eliminate this dusty medium" Professor Smyth concludes, "would be of the utmost consequence to the further improvement of astronomical observation, and may be considered the greatest and most subtile difficulty which the observer has to deal with; and it is probably general over the world, as on the South African mountains, at heights of 5600 feet, the phenomenon was almost at notable as on Guajara. From Dr. Mason's observations of solar radiation in Madeira, and from the relations given to me by inhabitants of Teneriffe, as to the periods of the year when the Peak is seen most clearly, I am disposed to think that there is least of this dust in the atmosphere in the latter end of the winter and the earlier part of the spring." (Report, or 'Phil. Trans.,' 1858, pp. 481, 482, 486–488, 499.)

Professor Smyth found it almost impossible to collect particles of the dust-haze for examination. Some of it, however, deposited at Guajara, he found to be scales from butterflies' wings. He also obtained a specimen of atmospheric dust which had fallen all over the Canarian islands, and another which had fallen at sea. By the microscopical examination of these, with a power of 400 linear, hardly anything could be made out but particles of sand. "The colour of either was mostly an ochry yellow with an occasional bright red, more rarely a green fragment; but nothing organic could be clearly distinguished of a diatomaceous character; the forms of almost all the particles being like quartz rocks in miniature." ('Report,' pp. 570, 571.)

From its characters and the concomitant phenomena, it may be inferred that the haze described in the following extract from Dr. Joseph D. Hooker's 'Himalayan Journals' (vol. ii. p. 409), is the dust-haze, occurring at altitudes in the Himalaya, nearly corresponding to those at which it exists, as we have seen, over the island of Teneriffe, and on the mountains of South Africa. "Two phenomena particularly obstruct radiation in Sikkim—the clouds and fog from the end of May till October, and the haze from February till May. Two months alone are usually clear; one before and one after the rains, when the air, though still humid, is transparent. The haze has never been fully explained, though a well-known phenomenon. On the plains of India, at the foot of the hills, it begins generally in the forenoon of the cold season, with the rise of the west wind; and, in February especially, obscures the sun's disc by noon; frequently it lasts throughout the twenty-four hours, and is usually accompanied by great dryness of the atmosphere. It gradually diminishes in ascending, and I have never experienced it at 10,000 feet; at 7000, however, it very often, in April, obscures the snowy ranges thirty miles off, which are bright and defined at sunrise, and either pale away, or become of a lurid yellow-red, according to the density of this haze, till they disappear at 10 a.m. I believe it always accompanies a south-west wind (which is a 'deflected current of the north-west) and dry atmosphere in Sikkim."

Hermann Schlagintweit has noticed the diminution of the solar radiation by the dust-storms of India, and observed a peculiar coloration of the sun, which he thinks is their regular concomitant when the air has lost a certain amount of transparency. "In dust-storms," he remarks, "the sky has," as in fogs, "a decidedly reddish colour, which in this case is that of the dust itself, but the sun's disc is blue, a phenomenon evidently connected with the suspension of solid particles in the air. I observed this colour best on the 6th of April 1856, at Futtehpore. The hot wind lasted from 12h. 45m. to 6h. 10m. p.m., and stopped very suddenly after sunset. The sun was very much obscured as early as 1 p.m., and had then assumed this blue appearance so decidedly, that it looked like the sun's disc seen through a dark-blue glass; the shadow of a thin cylinder falling on white paper was nevertheless well defined and reddish, showing that the illuminated paper had received rays of the (complementary) bluish colour. The blue colour of the sun, though the light was gradually diminished, lasted until 5h. 19m. p.m., when the sun had a height only of about 15 degrees; then the disc soon disappeared entirely behind the clouds of dust. . . . . . The temperature of the air diminished with the increase of the wind and discoloration of the air." ('Journ. of the Asiat. Soc. of Bengal,' vol. xxv., 1856, pp. 564, 565.) Whatever dependence, however, the blue colour of the sun may have upon the presence of solid particles in such cases, its cause, in other instances, is certainly a particular condition of the aqueous vapour in the air. [Meteors; Meteorology; Volcanoes; Winds.]

DUTCH LIQUID. [Ethyline.]

DUTY. [Right.]

DUUMVIRI, the name given to various magistrates in the republic of Rome, as well as in the colonia and municipia, who were elected in pairs for the discharge of any class of duties. We find the name applied to six different sets of functionaries at different periods. The first duumvirate on record was composed of the two judges of blood (*duumviri perduellionis*), appointed by Tullus Hostilius for the trial of P. Horatius, indicted for the murder of his sister, a crime of so great a nature as to be deserving of capital punishment (*perduellio*). The criminal condemned to death, as the lictor appeared with the fatal cord, claimed his right of appeal to the people, which being allowed him, he was acquitted, as Livy says, by them, "admiratione magis virtutis quam jure causæ." (Liv. i. 26.) This office was exercised by Tarquinius Superbus alone, for tyrannical purposes (Liv. i. 49), and afterwards by the consuls (Liv. ii. 5), who were indeed a duumvirate. Whether these *duumviri* were the same as the *quæstores parricidii*, as Niebuhr supposes, or whether they were distinct official personages during the kingly dynasty, is a question involved in the same obscurity as most other points relating to this period of Roman history. It certainly would appear that the two terms are confounded by ancient writers, some calling the judges appointed to preside at the trial of capital offences quæst. parric. others calling them duum. perduel. (cf. Liv. i. 26, d. 1, 2, 2, 23, and Festus *sub voc. parici et sororium*). But there is no doubt that they were distinct officials after the fall of the kingly power, and in the republican times, for while the one set, the quæstores, were regularly appointed by the year, the others were rarely and only on great occasions summoned to work. (cf. Liv. ii. 41, vi. 20; Dion Cass. xxxvii. 27; Aul. Gel. xvii. 21, and Cic. Pro Rabicio, c. iv. 2.) The *duumviri sacrorum*, who took care of and interpreted the Sibylline Books, were also a very ancient magistracy, ascribed by the old legends to the last Tarquin, and summoned into being on such dreadful emergencies as Livy records. (Liv. iv. 21.) Niebuhr thinks ('Hist. of Rome,' i. p. 504, Engl. tr.) that the number was dictated by a wish to deal evenly with the first two tribes, the Ramnes and the Tities. Besides these there were the *duumviri jure dicundo*, who were the highest magistrates in the municipal towns and colonies (cf. Cic. Agr. Leg. ii. 34, D. 2, 3, D. 15, 1. 3, § ult. D. 47, 10, 13, 5), sometimes called consuls (Cic. in Pison. cxi.), and sometimes even dictator and quæstor. Their jurisdiction, according to Savigny, was, under the republic, unlimited in civil matters, but was restricted within the limits mentioned in the digest and code in Imperial times. The *duumviri quinquennales*, or the censors in the municipal towns; distinct personages from the above magistrates; the *duumviri* specially appointed for the purpose of building or dedicating temples (Liv. i. 28, xxii. 88); and the *duumviri navales*, who were two officers, first elected in the year 436 A.U.C. (Liv. 'Epit.' lib. xii.; Niebuhr's 'Römische Geschichte,' translated by W. Smith and L. Schmitz, edit. 1851, vol. iii. p. 241.) Their duty was to collect, equip, man, and command the fleets of the republic. (Liv. ix. 30; xl. 18 and 26.) At the time of the first Runic war the office no longer existed.

DWARF is a technical term employed by gardeners to distinguish fruit-trees whose branches proceed from close to the ground from *riders* or standards whose original stocks are several feet in height.

DWARFING TREES. Nature, in many respects, can be made to deviate from her ordinary course of procedure, in order to be subservient to the purposes of men. In nothing is this fact more apparent than in the various modes of dwarfing trees.

The trees of our orchards and forests, for example, which grow naturally to a considerable size, can be made to assume all the appearances of maturity and age while only a few feet high; a forest in miniature can thus be created, which has a very grotesque and curious appearance. There are various methods of producing this effect; such as selecting peculiar kinds of stocks and grafting upon them. For example, if the pear-tree be grafted upon the quince stock, or the peach upon the plum, their growth is very much retarded, and their ultimate size is comparatively small; the same effect is produced upon all other trees where there is a difference between the tissue of the stock and that of the scion which has been grafted upon it; or if dwarf varieties be grafted upon stocks of a similar constitution, though taller in growth, the former will still retain their original character. Again, if the branches be bent, and the flow of the sap in any way impeded, or if a quantity of the fibrous roots be cut away, and nourishment more sparingly supplied to the branches, we arrive at the same results.

Sometimes trees are dwarfed by very severe pruning, particularly if this operation be performed in summer; and, although they evidently try for a length of time to overcome this obstruction to their natural size, yet they eventually assume a dwarfed and stunted habit, which, with a little care, may be retained for many years. The Chinese in particular have carried this practice to a great extent, and they ornament their fanciful gardens with miniature forests of elms, junipers, and other timber trees.

The methods of dwarfing employed by the Chinese are the following: young trees of various sorts are planted in flat porcelain vessels, and receive only so much water as is sufficient to keep them alive; in a very short time the pots are completely filled with roots, which, being hemmed in on all sides, cannot obtain a sufficient quantity of nutriment, and, as a matter of course, the growth of the stem and branches is thus impeded. The Chinese also pinch off the ends from the young shoots, mutilate the roots, lacerate the bark, tie down the branches, and break many of them half through; in short, by every means in their power they contrive to check growth, so that, stunted and deformed by these means, the trees soon assume all the marks of age when only two or three feet high.

There is another method of producing dwarf trees, which may be termed accidental: namely, selecting dwarf individuals and obtaining seed from them. It is well known that when the young seed is fertilised by the influence of the pollen belonging to its own flower, or to the same plant upon which it grows, the future progeny so produced partakes generally in a large degree of the nature of the parent from which it originates. Now, if seed be carefully obtained from a variety rather more dwarf than usual, some of the plants produced by that seed will be somewhat more dwarf than their parents. The most dwarfed individuals again selected for seed will originate a race yet more dwarf than themselves; and thus, with patience and by successive generations, a variety only a few inches high may be obtained from a species two or three feet high, or even higher. This is the origin of dwarf roses, dahlias, and other common cultivated flowers.

With the exception of this last-mentioned method, all the others, however different they may seem, proceed from the same principle; for whether we graft upon stocks whose tissue differs in organisation from the scion, or whether we bend the branches, or cut or confine the roots, we prevent the full flow of the sap in all such cases, and thus advance the age of puberty and bring on a fruit-bearing state. When plants have arrived at this stage of existence, all their energies are directed to the formation of fruit; hence forcing a tree into an early state of fruit-bearing is almost synonymous with dwarfing it.

DYEING is the art of staining textile substances with permanent colours. To cover their surfaces with colouring matters removable by daily use would be to apply a pigment rather than to communicate a dye. Dye-stuffs can penetrate the minute pores of vegetable and animal fibres only when presented to them in a state of solution, and they can constitute fast colours only by passing afterwards into the state of insoluble compounds with the fibres themselves. Dyeing thus appears to be altogether a chemical process, and to require for its due explanation and practice an acquaintance with the properties of the elementary bodies, and the laws which regulate their combinations. It is true, nevertheless, that many operations of this, as of other chemical arts, have been practised from the most ancient times, long before any just views were entertained of the nature of the changes that took place. Mankind, equally in the rudest and most refined state, have always sought to gratify the love of distinction by staining their dress, sometimes even their skin, with gaudy colours. Moses speaks of raiment dyed blue, and purple, and scarlet, and of sheepskins dyed red,—circumstances which indicate no small degree of tinctorial skill. He enjoins purple stuffs for the works of the tabernacle and the vestments of the high priest.

In the article CALICO PRINTING we have shown from Pliny that the ancient Egyptians cultivated that art with some degree of scientific precision: seeing that they knew the use of mordants, or of those substances which, though they may impart no colour themselves, yet enable white cloth to absorb colouring drugs. Tyre, however, was the nation of antiquity which made dyeing its chief occupation and the staple of its commerce. There is little doubt that purple, the sacred symbol of royal and sacerdotal dignity, was a colour discovered in that city, and that the discovery and use of the dye contributed to the opulence and grandeur of the place. Homer marks the value as well as antiquity of this dye, by describing his heroes as arrayed in purple robes. Purple habits are mentioned among the presents made to Gideon by the Israelites from the spoils of the kings of Midian. The juice employed for communicating this dye was obtained from two different kinds of shell-fish, described by Pliny under the names of *purpura* and *buccinum*; and was extracted from a small vessel, or sac, in their throats, to the amount of only one drop from each animal. A darker and inferior colour was also procured by crushing the whole substance of the buccinum. A certain quantity of the juice collected from a vast number of shells being treated with sea-salt, was allowed to ripen for three days; after which it was diluted with five times its bulk of water, kept at a moderate heat for six days more, occasionally skimmed to separate the animal membranes, and when thus clarified was applied directly as a dye to white wool, previously prepared for this purpose by the action of lime-water, or of a species of lichen called fucus. Two operations were requisite to communicate the finest Tyrian purple: the first consisted in plunging the wool into the juice of the purpura; the second, into that of the buccinum. Fifty drachms of wool required one hundred of the former liquor, and two hundred of the latter. Sometimes a preliminary tint was given with coccus, the kermes of the present day, and the cloth received merely a finish from the precious animal juice. The colours, though probably not nearly so brilliant as those producible by our cochineal, seem to have been very durable, for Plutarch says, in his 'Life of Alexander' (chap. 36), that the Greeks found in the treasury of the King of Persia a large quantity of purple cloth, which was as beautiful as at first, though it was 190 years old. The difficulty of collecting the purple juice, and the tedious complication of the dyeing process, made the purple wool of Tyre so expensive at Rome that in the time of Augustus a pound of it cost nearly 30*l.* of our money. Notwithstanding this enormous price, such was the wealth accumulated in that capital, that many of its leading citizens decorated themselves in purple attire, till the emperors arrogated to themselves the privilege of wearing purple, and prohibited its use to every other person. This prohibition so much discouraged the art of dyeing purple as eventually to occasion its extinction, first in the western and then in the eastern empire, where, however, it existed in certain imperial manufactories till the 11th century.

Dyeing was little cultivated in ancient Greece. The people of Athens wore, generally, woollen dresses of the natural colour. But the Romans must have bestowed some pains upon this art. In the games of the circus, parties were distinguished by colours. Four of these are described by Pliny,—the green, the orange, the gray, and the white. The following ingredients were used by their dyers: a crude native alum mixed with copperas, copperas itself, blue vitriol, alkanet, lichen rocellus or archil, broom, madder, woad, nut-galls, the seeds of pomegranate, and of an Egyptian acacia.

The moderns have obtained from the New World several dye-drugs unknown to the ancients, such as cochineal, quercitron, Brazil wood, logwood, annatto, &c.; and they have discovered the art of using indigo as a dye, which the Romans knew only as a pigment. But the vast superiority of our dyes over those of former times must be ascribed principally to the employment of pure alum and solution of tin as mordants, either alone or mixed with other bases; substances which give to our common dye-stuffs remarkable depth, durability, and lustre. Another improvement in dyeing of more recent date is the application to textile substances of metallic compounds, such as Prussian blue, chrome yellow, manganese brown, &c.

Indigo, the innoxious and beautiful product of an interesting tribe of tropical plants, which is adapted to form the most useful and substantial of all dyes, was actually denounced as a dangerous drug, and forbidden to be used, by our parliament in the reign of Queen Elizabeth. An Act was passed authorising searchers to burn both it and logwood in every dye-house where they could be found. This Act remained in full force till the time of Charles II.; that is, for a great part of a century. The purpose of this statute was professedly to check the use of two dye-drugs supposed to be dangerous; but it is probable that the legislation was suggested by the growers or makers of certain English drugs, to favour their monopoly.

Mr. Delaval made many ingenious experiments to prove that the particles of dye-stuffs possess no power of reflecting light, and that, therefore, when viewed upon a dark ground, they all appear black, whatever colour they may exhibit when seen by light transmitted through them. He hence inferred that the difference of colour shown by dyed cloths is owing to the white light which is reflected from the textile fibres being decomposed in its passage through the superinduced colouring particles. We think it more than probable that this conclusion is in some respects incorrect, and that the aluminous, iron, and tin bases form combinations with dye-stuffs which are capable of reflecting light, independent of the reflection from the fibre itself. There can be no doubt, however, that this latter reflected light adds greatly to the brightness of the tints, and that the whiter the textile substance is, the better dye it will, generally speaking, receive. It is for this reason that scouring or bleaching of the stuffs is usually prescribed as a process preliminary to dyeing.

Bergman appears to have been the first who referred to chemical affinities the phenomena of dyeing. Having plunged wool and silk into two separate vessels, containing solution of indigo in sulphuric acid diluted with a great deal of water, he observed that the wool abstracted much of the colouring matter, and took a deep blue tint, but that the silk was hardly changed. He ascribed this difference to the greater affinity subsisting between the particles of sulphate of indigo and wool, than between these and silk; and he showed that the affinity of the wool is sufficiently energetic to render the solution colourless by attracting the whole of the indigo, while that of the silk can separate only a little of it. He thence concluded that dyes owed both their permanence and their depth to the intensity of that attractive force.

We have therefore to consider in dyeing the play of affinities between the liquid medium in which the dye is dissolved and the fibrous substance to be dyed. When wool is plunged in a solution containing cochineal, tartar, and salt of tin, it readily assumes a beautiful scarlet hue; but when cotton is subjected to the same bath it receives only a feeble pink tinge. Dufay took a piece of cloth woven of woollen warp and cotton weft, and having exposed it to the fulling-mill in order that both kinds of fibre might receive the same treatment, he then subjected it to the scarlet dye; he found that the woollen threads became of a vivid red, while the cotton continued white. By studying these differences of affinity, and by varying the preparations and processes, with the same or different dye-stuffs, we may obtain an indefinite variety of colours of variable solidity and depth of shade.

Dye-stuffs, whether of vegetable or animal origin, though susceptible of solution in water, and, in this state, of penetrating the pores of fibrous bodies, seldom possess alone the power of fixing their particles so durably as to be capable of resisting the action of water, light, and air. For this purpose they require to be aided by another class of bodies, already alluded to, which bodies may not possess any colour in themselves, but serve in this case merely as a bond of union between the dye and the substance to be dyed. These bodies were supposed, in the infancy of the art, to seize the fibres by an agency analogous to that of the teeth of animals, and were hence called *mordants*, from the Latin verb *mordere*, to bite. But the term derived from it has gained such a footing in the language of the dyer that all writers upon his art are compelled to adopt it.

Mordants may be regarded, in general, as not only fixing but also occasionally modifying the dye, by forming with the colouring particles an insoluble compound, which is deposited within the textile fibres, Such dyes as are capable of passing from the soluble into the insoluble state, and of thus becoming permanent, without the addition of a mordant, have been called substantive, and all the others have been called adjective colours. Indigo and tannin are perhaps the only dyes of organic origin to which the title substantive can be applied, and even they probably are so altered by atmospheric oxygen, in their fixation upon stuffs, as to form no exception to the true theory of mordants.

Mordants are of primary importance in dyeing; they enable us to vary the colours almost indefinitely with the same dye, to increase their lustre, and to give them a durability which they otherwise could not possess. A mordant is not always a simple agent; but in the mixture of which it consists various compounds may be formed, so that the substances may not act directly, but through a series of transformations. The China blue process [Calico Printing] affords a fine illustration of this truth. Sometimes the mordant is mixed with the colouring matters; sometimes it is applied by itself first of all to the stuff; and at others both these methods are conjoined. We may dye successively with liquors containing different substances, which will act differently according to the different mordants successively employed. One solution will give up its base to the stuff only when aided by heat; another acts better and more uniformly when cold, though this is a rarer case.

When a mordant consists of a changeable metallic oxide, as of iron or tin, unless great nicety be used in its application, either no effect or an injurious one may be produced upon the dye. All these circumstances prove how necessary it is for the dyer to be thoroughly versed in chemical science. Each of the great dye-works in Alsace, celebrated for the beauty and fixity of their colours, is superintended in the laboratory department by a gentleman who has studied chemistry for two or more sessions in the universities of Paris or some other eminent schools. The English cotton dyers, twenty or thirty years ago, were far inferior in skill to those of France; but they have recently made great advances. Now many of the Manchester houses have chemists (some of them men of great attainments), and no doubt in other towns also; and for smaller establishments there are professional consulting chemists.

The first principle of dyeing fast colours, we have seen, consists in causing the colouring matter to undergo such a change, when deposited upon the wool or other stuffs, as to become insoluble in the liquor of the dye-bath. The more powerfully it resists the action of other external agents, the more solid or durable is the dye. Generally speaking, a piece of well-dyed cloth should not be materially affected by hot water, by soap and water, by exposure to air and light, by dilute nitric acid, or even by very dilute aqueous chlorine.

In the following details concerning the art of dyeing we shall consider principally its application to wool and silk, having already treated, in the article Calico Printing, of what is peculiar to cotton and linen.

The operations to which wool and silk are subjected preparatory to being dyed are intended, 1, to separate certain foreign matters from the animal fibre; 2, to render it more apt to unite with such colouring particles as the dyer wishes to fix upon it, as also to take therefrom a more lively and agreeable tint, as well as to be less liable to soil in use. The matters foreign to the fibre are either such as are naturally associated with it during its production by the animal, such as have been added to it in the spinning and weaving operations, or such as have been accidentally applied.

Silk is scoured by means of boiling in soap and water, whereby it is freed from a varnish, improperly called gum. This consists of an azotised compound, which may be separated in a gelatinous form by cooling the hot water saturated with it. It constitutes about a fourth part of the weight of most raw silks, and contains a little colouring matter of an orange or yellow hue. When silk is required to be extremely white, either to be woven in that state, or to receive the brightest and purest dyes, it should be exposed to the action of humid sulphurous acid. For dark dyes, silk need not be scoured at all, in which case it preserves its whole weight. Wool is first washed in running water to separate its coarser impurities; it is then deprived of its *yolk* (a species of animal soap secreted from the skin of the sheep) either by the action of ammoniacal urine, by soap and water, or by a weak lye of carbonate of soda. Common wools lose in this way from 20 to 50 per cent. of their weight, and merino wools still more. They receive their final bleaching by the fumes of burning sulphur, or by aqueous sulphurous acid.

Wools present remarkable differences in their aptitude of combining with dye-stuffs, depending upon the different structure of the imbrications of the filaments. The colouring particles seem to insinuate themselves at these pores with greater or less facility, and to be retained with greater or less force, according to the magnitude and form of the orifices. This difference in dyeing, therefore, is not due to the repulsive action of fatty matter, as has been commonly supposed, since it still exists in wool even when every particle of grease has been removed from it by alcohol and ether. A boiling in a solution of bran is often had recourse to, in order to make wool take the dye more readily and equally; but a hot lye containing one-half per cent. of crystallised carbonate of soda answers much better. When heated to the temperature of 140° or 150° Fahr., the wool should be immersed in that liquor, and turned about for half an hour. The wool receives a faint yellowish tint from this bath, but it speedily becomes white on exposure to air; or it may be whitened at once by passing it through tepid water containing a very small quantity of muriatic acid. The yellow colour is most probably occasioned by the reaction of the sulphur and iron contained in the wool.

According to the experiments of Thenard and Roard, alum combines with wool in the state of a salt, without separation of its acid constituent. Wool boiled with a solution of tartar decomposes a portion of it completely; some of the acid and a little of the tartar combine with the wool, while a neutral tartrate of potash remains in the bath. This fact is interesting in reference to the scarlet dye, showing the important part which tartaric acid here performs.

Tinctorial colours are either simple or compound. The simple are black, brown or dun, blue, yellow, and red; the compound are gray, purple, green, orange; and other numerous modifications, all producible by the mixture of simple colours. We shall treat here of only *black* and *brown*, in the present place.

1. *Black.*—If we apply to a white stuff blue, red, and yellow, in certain proportions, the resulting colour will be black. Proceeding on this principle, Castel asserted that 15 parts of blue, 5 of red, and 3 of yellow, will produce a perfect black; but in making this statement he was influenced rather by theoretical than practical considerations. In fact he has afforded us no means of procuring these simple colours in an absolute state. It is undoubtedly true, however, that red, yellow, and blue, employed in adequate quantities, will produce black; because they will together absorb, or obstruct the passage of all coloured light, or, in other words, cause its total privation, whence blackness must result. If we suppose a piece of cloth, to which these three colours have been communicated, but not in such proportions as to produce a pure black, we shall have a tint corresponding to the colour that is in excess; as, for example, a blue, violet, red, or greenish *black*; and with paler tints we shall have a bluish, violet, red, or greenish *gray*.

Gall-nuts, and a salt of iron, so generally employed for the black dye, give merely a violet or greenish-gray, and never a pure black. The pyrolignite of iron, which contains a brown empyreumatic matter, produces a brown inclining to greenish-yellow in light shades, and to chestnut-brown in dark hues. By galling cotton and silk, after a bath of pyrolignite of iron, and repeating the processes several times, a tolerably pure black may be procured. Galls, logwood, and a salt of iron (copperas) produce merely a very deep violet-blue; but if they be applied to wool in a hot bath, with frequent exposure to air, the logwood induces a brownness which is favourable to the formation of black.

The black dye for hats is communicated by logwood, copperas, and verdigris mixed in certain proportions in the same bath; from that mixture there results a vast quantity of an ochreous muddy precipitate, amounting to 25 per cent. of the copperas employed. This mud forms a deposit upon the hats which not only corrodes the fine beaver filaments, but causes both them and the felt to turn speedily of a rusty brown. A well-dyed black hat should retain its original tint as long as it lasts,—a condition seldom realised. Beaver hats, however, to which these remarks refer, have been almost superseded by those covered with silk plush, to which a different process of dyeing applies.

Since gall-nuts give a blue precipitate with the peroxide salts of iron, they are occasionally replaced by sumach, bablah, &c.; but account should be taken in this substitution of the proportions of red or yellow colouring matter in these substances, relatively to the tannin which alone forms the blue precipitate. When a black of the best possible shade is to be given, the wool should be first grounded with indigo, then passed through a bath of logwood, sumach, and protosulphate of iron (green copperas). Sumach and nut-galls may also be employed in the proportion of 6 to 2½; or the sumach may be replaced by nut galls, if they be equal to one-third of the sumach prescribed. A good black may be dyed upon an indigo ground with 100 lbs. of wool, by taking 200 lbs. of logwood, 60 lbs. of sumach, 2½ lbs. of galls, and 20 lbs. of green copperas; and giving three heats of two hours each to the wool, with airings between. A good black, without an indigo blue ground, may be given to 100 lbs. of wool, by boiling it in a bath of 25 lbs. of alum and 674 of tartar; grounding it with weld and madder; then passing it through a bath of 200 lbs. of logwood, 60 of sumach, and 2½ of galls; taking it out, adding to the bath 20 lbs. of copperas; lastly, giving it three heats of two hours each time.

The best French black, according to Hellot, may be given to wool by first dyeing it a dark blue in the indigo vat; then washing and fulling it; then, for every 50 lbs., putting into the copper 8 lbs. of bruised galls, and as much logwood tied up in a coarse canvas bag, and boiling them for twelve hours. One-third of the bath thus prepared is to be transferred into another copper with 1 lb. of verdigris, and the wool or stuff is to be worked in this solution without intermission for two hours: the bath being kept hot, but not boiling. After taking out the stuff, another third part of the first bath is to be added along with 4 lbs. of green copperas; the fire must be lowered while this salt is being dissolved, and the bath being refreshed with a little cold water, the stuff is to be worked through it for half an hour, and then aired. Lastly, the residuary third of the first bath is to be now introduced, taking care to squeeze the contents of the bag. From 8 to 10 lbs. of sumach are added; the liquor is just made to boil, then refreshed with some cold water; after which, a pound of green copperas being dissolved in it, the stuff is again passed through it for an hour. It is now taken out, aired, washed, then returned to the copper, and worked in the bath for another hour. It is next washed at the river and fulled. A finish is prescribed in the madder-bath.

The ordinary proportions used by the English black dyers for 100 lbs. of cloth, previously treated in the indigo vat, are about 5 lbs. of copperas, as much nut-galls bruised, and 30 lbs. of logwood. They first gall the cloth, and then pass it through the decoction of logwood in which the copperas has been dissolved. A finish of weld is often given after fulling; but this is of doubtful utility, especially when a little soap has been used in the fulling-mill. Vitalis prefers the pyrolignite of iron to the sulphate for the black dye, and says it produces a softer and more velvety colour—an opinion which some English chemists dispute.

The black dye vat, as it gets exhausted, is employed to dye grays of various shades.

Silk is dyed black in two methods, according to the market for which it is made. When sold by weight, as was formerly the practice at Tours, and is now with silk thread in this country, it is an object with the dyer to load it with as much colouring or other matter as possible. Sugar is at present much employed to falsify the weight of English silk thread, as any person may discover by applying a hank of it to his tongue. We have seen thread more than doubled in weight by this fraudulent device. Such silk is called *English black* by the French, who are not suffered to practise this deception. When silk is sold by superficial measure, on the other hand, it becomes the dyer's object to give it a black colour with as little weight of materials as possible. Hence the distinction well known in the trade of heavy and light silks. In this, as in many similar examples of adulteration, a desire on the part of some dealers to undersell their neighbours probably produced the evil in the first instance; and then the others joined in the fraud for self-defence.

The 25 per cent. of weight which silk has lost in scouring may be in a great measure recovered by giving it a sufficient dose of galls. For this purpose a bath is made by boiling galls equal to two-thirds or three-fourths the weight of the silk for three or four hours in a sufficient quantity of water, and then letting the decoction settle for two hours. The silk must be steeped in this bath from twenty to thirty-six hours, and then washed in clear water. The first galling is, however, commonly given with a bath somewhat spent; and for heavy blacks generally upon unscoured silk. Several successive immersions in gall-baths, and of considerable duration, are usually given to silk, with intervening washings and wringings at the peg.

The silk dyers keep up from year to year a black vat, often of very complex composition. The essential constituents of the vat are sulphate of iron and gum; but many vegetable matters, as well as filings of iron, are usually added. This bath being heated short of boiling, and then allowed to settle for about an hour, the silks are worked in it with much manipulation, occasional wringing out, airing, and redipping. As the copperas and gum get exhausted, the bath must be replenished with these ingredients in due proportions. The addition of logwood and verdigris is very useful to the black silk dye, and is now generally made. A ground of walnut peels is a good and cheap preparation for this dye.

2. *Brown or dun colour.*—This dye is not so common in England as on the Continent, where the colouring matter is generally produced at a very cheap rate by steeping ripe walnuts with their peels in water for a year or two, till the vat acquires a deep brown colour and a fetid smell. This infusion affords very agreeable and permanent brown tints without any mordant; while it preserves the downy softness of the wool, and requires but a simple and economical process. In dyeing with this infusion, a quantity of it proportional to the shade required is to be put into the copper, diluted with water, and made to boil. The cloth or yarn needs merely to be moistened beforehand with tepid water, to be then plunged in the bath, and turned about till sufficiently dyed. Some dyers, however, give the stuff a preparatory mordant of alum, and leave it to drain for twenty-four hours before subjecting it to the bath of walnut-peels.

Sumach is usually employed in this country to dye fawns, and some browns; but more beautiful browns may be given to woollen stuffs by boiling them first with one-fourth their weight of alum and some tartar and copperas, washing, and afterwards dyeing them in a madder bath. The shade of colour depends upon the proportion which the copperas bears to the alum.

A good brown may also be obtained by mordanting every pound of the stuff with two ounces of alum and one ounce of common salt in a boiling bath; and then dyeing it in a bath of logwood to which some copperas has been added; or the stuff dyed red in the madder bath may be turned about in the black dye vat till the required shade be produced.

The finest browns are produced by boiling each pound of the wool with two ounces of alum, dyeing it in a cochineal bath, and then transferring it to a bath containing a little cochineal darkened with acetate of iron. Instead of cochineal, the archil or cudbear bath may be used, with a little sumach or galls. This forms a cheaper but a more fugitive colour.

A beautiful brown tint, on wool or silk, may be obtained by first giving a pale blue shade in the indigo vat, then mordanting with alum, washing and finishing in a madder bath till the proper brown be brought up. The Saxon blue vat may also be used. If the stuff be mordanted with alum and tartar, then boiled in a madder bath, afterwards in one of weld or fustic, to which more or less copperas has been added, we shall have a mordore, cinnamon, or chestnut brown. By the combination of olive shades with red, bronze tints may be produced. For 25 lbs. of stuff a bath containing 4 lbs. of fustic will suffice. Boil the wood two hours, then turn the stuff in the bath for an hour, take it out, and drain. Add to the bath 4 or 6 ounces of copperas and a pound of madder or sandal-wood; then work the stuff in it till the wished-for shade is attained.

Silk may receive a ground of annatto, and then be dyed in a bath of logwood or Brazil wood, whereby a fine brown tint is obtained. Catechu is used for giving a bronze and brown to cotton goods. [CALICO-PRINTING.] Blue colours are dyed with indigo, Prussian blue, and woad; yellows with fustic, Persian berries, quercitron, turmeric, and weld; reds with archil or cudbear, Brazil wood, cochineal, kermes, lac, logwood, madder, safflower, or carthamus. The purple, green, and orange dyes are produced by various applications of cochineal, indigo, quercitron bark, &c.

M. Roard, long the skilful director of the Gobelins' dye-works, has observed that copper boilers exercise a considerable influence upon delicate dyes. He found that ammonia causes a blue precipitate in the alum bath made in such boilers; while it causes merely a white precipitate in the same bath made in vessels of glass, porcelain, and tin. When wool is kept for some hours in boiling water contained in a copper vessel, it acquires a greenish-gray tint,—a result increased by the ordinary mixture of alum and tartar. If into this bath white wool be plunged, it receives a greenish-yellow, or sometimes an ochrey hue. These observations of M. Roard are of considerable importance, and should lead dyers to employ tin or at least brass boilers instead of copper ones for all vivid colours. Heating with steam, either by double vessels, by straight or spiral tubes, ought on all occasions to be preferred in the dye-house to naked fires, which seldom fail to carbonise some portions of the vegetable or animal matters, and thereby to degrade the colours. The top edge or surface of the boilers should be about 3½ feet above the floor; this being a height which the workmen find most convenient for their manipulations when they stand upon a step 8 or 10 inches high.

The stuffs mordanted with alum should not be transferred to the bath immediately, but be allowed to drain and air for twenty-four hours. The colours are thereby rendered more lively than when dyed soon after the aluming. As experience has proved that an old alum bath is better than one fresh made, it should not be thrown away, but be strengthened or refreshed by the requisite additions of alum and tartar. It is certain that wools boiled in alum the second time, are more beautiful than those boiled in it the first time.

The methods of dyeing black and brown sufficiently explain the general principles, and we therefore conclude with a few observations of a general nature.

Mr. Solly, in communications recently made to the Society of Arts, has drawn attention to several matters having an important relation to the improvement of the art of dyeing. We will merely advert to two of these subjects,—the desirability of studying the chemistry of agriculture in relation to the growth of dye-plants; and the saving of freight in importing only the essential parts of dye-drugs, instead of the whole bulk.

Mr. Solly, in relation to the first of these two subjects, the influence of soil and culture on the chemistry of dye-plants, said, "It was observed that some of the madder grown near Avignon was inferior in the richness and brilliancy of its colour to that produced in other districts. The proprietor being anxious to discover the cause, was led to institute a chemical examination of the soil of his own land, in comparison with that of some of the best madder farms. The result showed that his soil was deficient in lime, while all the others contained it. He was therefore induced to give his land a good dressing of lime; and the result fully justified this course, for in the next year the crop of madder was inferior to none."

The same authority, in relation to the bulkiness of dye-materials, said, "Dye-stuffs are for the most part bulky and heavy substances, the carriage of which for any distance, by land or even by water, makes a very serious addition to their cost; consequently every mode of increasing the proportion per cent. of colouring matter is worthy of consideration; and those modes of preparation are best which yield the largest quantity of colour, and the least quantity of useless fibrous matter. Owing to the judicious manner in which the Chinese safflower is collected, it contains far more of the fine red colouring matter, and is consequently worth four or five times as much in the market as the best Bengal safflower; in addition to which, for want of due care in the drying, the latter is sometimes so much injured during the sea voyage as to be deteriorated fifty per cent. The loss thus sustained is often set down to the nature of the drug, and not to the careless habits of those employed in collecting it. When we remember how many thousand tons of dye-woods are annually imported, and how many thousand tons of it are absolutely useless woody fibre, we cannot help coming to the conclusion that here chemical science might be applied with great advantage; and that if colonists could be taught how to extract and concentrate the true colouring principle of these woods, much unprofitable labour and expense might be spared. Nay, more, the concentrated dye-stuff might be profitably imported from places from which the cost of carriage would altogether prevent the importation of the dye-stuff in its raw state. This is a matter of great practical importance, and one which has not yet received that attention it deserves. There are no doubt difficulties in the way; but after the many triumphs which man has achieved, we surely need not be deterred by any ordinary difficulties."

To the above we may add a few valuable observations, made by Mr. Simmonds in his 'Commercial Products of the Vegetable Kingdom,' on the useful qualities of many simple and well-known plants, and other substances, as dye materials. "The beauty of the dyes given by common materials, in the Highlands of Scotland, to some of the cloths which were exhibited [at the Great Exhibition of 1851], should lead our botanists and chemists to examine more closely than they have hitherto done, the dye-stuffs that might be extracted from British plants. Woad, and the dyers' yellow wood, are both well known. A piece of tweed, spun and woven in Ross-shire, was dyed brown and black by such cheap and common dyes as moss and alder-bark; and the colours were unexceptionable. Sutherlandshire tweeds and stockings, possessing a rich brown colour, were produced with no more valuable dye than soot; in another piece, beautifully dyed, the yellow was obtained from stony rag; brown from the crops of young heather; and purple from the same, but subjecting the yarns to a greater action of the dye than was necessary to produce brown. There is very little doubt but that beautiful and permanent dyes, from brown to a very rich purple, might be cheaply produced by scientific preparations of the common heather. The inhabitants of Skye exhibited cloth with a peculiarly rich dye, obtained from the Crobal moss."

It has been shown in former articles [BLEACHING; CALICO PRINTING] that the legislature has sought to throw a shield of protection around the women and children employed in bleach and print works; that this attempt succeeded so far as concerned print works; but that bleach works still remain exempt from the operation of the Factory Acts. We have now to add that dye works are in the same category as bleach works. In the years 1854-5-6-7, both classes of establishments were subject to many parliamentary discussions, and to inquiries by commissioners—ending by a postponement of all legislation thereon.

DYKE. A structure of earth, or of masonry, for the purpose of resisting the inroads of the sea, or of any large body of water; or for the purpose of guiding and controlling the action of the floods of rivers, or of preventing the tidal action of rivers, or of arms of the sea, from exercising itself in a way which might be injurious to the surrounding lands. The construction and form of dykes must evidently depend to a great extent upon the position in which they are placed, and upon the nature of the materials of which they are to be composed; and the principles to be followed in designing them must equally depend upon the local conditions they will have to fulfil. It will therefore be preferable to treat the whole subject of river or fen-dykes under the head of RIVER IMPROVEMENTS; and that of sea-dykes under the head of SEA DEFENCES.

DYNAM. In estimating the effect of mechanical labour, it is desirable to have some idea of a simple unit well fixed in the mind. All who have studied the subject know the advantage there is in referring every kind of pressure to weight, and measuring it by the weight which will balance it. Thus if one hundred pounds weight will bend a spring into a certain position, we have no difficulty in substituting an opposite force to the weight for the recoil of the spring at the point of application. It is equally convenient to arrive at a distinct notion of a unit of useful effect in the workmanship of machines; but it may not at first be so apparent that the thing is practicable. Nevertheless, the theory of dynamics contains the means of showing that all the effects of a given power are convertible in the following manner. Exclude friction and useless resistances, and suppose that a steam-engine, for instance, will exhaust a certain quantity of fuel in raising a ton through a hundred feet, no power being thrown away. Suppose also that the same machine, with the same fuel, will completely expend the power of that fuel in drawing a certain iron cylinder into wire of a thousand times its length. Then, if a machine could be constructed which acts by the descent of a weight, and draws wire without any loss of power, the descent of a ton through a hundred feet would just be sufficient moving power to draw out the cylinder just mentioned to a thousand times its length. We do not of course mean to say that such freedom from loss of power exists. If, for example, a certain quantity of fuel were made to raise water by a steam-engine, and the water so raised were allowed to fall upon a wheel and grind corn, it is certain that the water would not grind so much corn as the steam-engine itself directly applied to that purpose. But this arises from useless increase of resistances, and from badness of adaptation: it is impossible to make all the water in a fall produce its utmost effect upon a wheel. But what we say is, that were it possible to make adaptation perfect, there exists in the water raised exactly the same capability of grinding corn that there is in the fuel which raised the water.

This being the case, we may consider any machine as simply applied to raising a weight, and look upon the weight raised as a dynamical synonym for any possible effect that the machine could have produced. And the theory further teaches us that the useful effect of any application of power varies jointly as the weight raised, and the height to which it is raised. Thus twice as much power must be expended to raise a double weight to the same height, or the same weight to a double height. Accordingly, the product of the number of pounds raised, and the number of feet to which it is raised, is a *relative* measure of the quantity of power. For example, a certain expenditure of force raises 70 pounds through 20 feet; what comparative expenditure will raise 120 pounds through 210 feet? The product 70 × 20 or 1400 is to the product 120 × 210 or 25,200 in the proportion of 1 to 18; accordingly, the second work requires 18 times the power of the first. Whether it shall be done by 18 engines, or by an application of 18 times as much power to one engine, is merely a question of adaptation.

We can convert the above relative measurement into an absolute form by assuming as a unit one pound raised through one foot; let this be called a *dynam*, or dynamical unit. Thus in the first job above mentioned, there are 1400 dynams of work to do. Whether it be considered as 1400 pounds raised through one foot, or one pound through 1400 feet, or 100 pounds raised through 14 feet, &c. &c., matters nothing: it is 1400 times as much work as one pound raised through one foot. Thus, what is commonly called a *horse-power* is meant by our engineers to signify 550 dynams in a second; a steam-engine which can raise one pound through 550 feet in every second is said to be of *one-horse power*.

This term was introduced by French writers, who called the effect of a cubic metre of water raised through one metre, a *dynamie* or *dyname*. Dr. Whewell ('Mechanics of Engineering,' 8vo, p. 150, Cambridge, 1841,) proposed to naturalise the term *dynam* as applied to our most convenient units, the pound and the foot.

It is for want of a distinct notion of this kind that many persons fall into the error about force and its effects, which lead them to contrive perpetual motions. But independently of this, there is a great practical utility in having a specific name for a quantity of work done, independently of all incidental circumstances; for something which should allow us a proper expression for the result of a quantity of fuel or other generator of force without the necessity of describing a particular mode of using the force. Watt was really the first who assumed, as a dynamic unit, the simple notion of one pound raised one foot; but he did not venture on a name, though the now common term, the *duty* of an engine, first used by him, has reference to the number of such simple units as may be obtained from the engine.* The late Davies Gilbert, in his paper 'On the expediency of assigning specific names to all such functions of simple elements as represent definite physical properties' (Phil. Trans., 1827), proposed to represent the product of the pounds raised and the feet through which they are raised by the term *efficiency*. But he did not go further, and assign a name to the unit of efficiency. This simple step, which is of more importance in the propagation of clear ideas than many persons will think it to be, is due to the French writers.

DYNAMETER. [MICROMETER.]

DYNA'MICS (δύναμις, force), a word of comparatively modern use, now universally adopted as signifying the science of matter in motion, as distinguished from *statics*, which relates to matter at rest. Under so general a term, our plan requires us simply to refer the reader to the several articles connected with the subject.

Dynamics may be divided into two distinct parts: the mathematical consideration of motion, without reference to any connection with its cause; and the experimental investigation of the connection between pressure and the motion produced by it, together with the mathematical exhibition of the laws under which the second is a consequence of the first. But for the purposes of classification, dynamics is better subdivided into (1) dynamics of a *particle*, and (2) dynamics of a *rigid body*. When the moving matter is considered as condensed into a single *particle*, the laws of its motion may be very accurately and conveniently traced under the following heads:—

(1.) The laws of motion—absolute and relative.
(2.) Collision and impact of moving particles.
(3.) Motion down inclined planes.
(4.) Motion under the action of central forces.
(5.) Curvilinear motion, as of projectiles.
(6.) Motion in resisting media.
(7.) Constrained motion, or motion of a particle along curved tubes, wires, &c.

But if the body be necessarily of some magnitude, and if it be rigid, that is, if its component particles, or its component parts (if it be a system), be supposed to bear, throughout the action, the same invariable position with respect to one another, then we have the following subdivisions of the dynamics of a *rigid body*:—

(1.) Motion about a fixed axis, as of pendulums.
(2.) Motion about a fixed point.
(3.) Motion of a *free* rigid body.
(4.) Motion of a rigid system.
(5.) Motion under the action of impulsive or instantaneous forces.

By referring therefore to such articles as COLLISION; MOTION;

---

* Or rather, according to Watt's view, the *power* is the quantity of work which an engine can perform in a given time; the *duty* is the quantity which it can perform by a given expenditure of fuel.

Motion, Laws of, &c. &c., the details of each subdivision will be clearly understood from the mathematical proofs and explanations there given. The history of dynamics is particularly connected with the names of Galileo, Huyghens, Newton, D'Alembert, and Lagrange, whose lives are given in the Biog. Div. See also on this point Mechanics, the general term under which statics and dynamics are included.

DYNAM'OMETER (δύναμις and μέτρον, measurer of power), a term which has been applied to an instrument which measures any thing to which the name of power has been given, whether that of an animal, or (to take a very different instance) of a telescope, only in the latter case it is termed a *dynameter*. [Micrometer.] We have also seen the incorrect term *dynometer*.

Dynamometrical instruments have been but little attended to in this country, but they have been used successfully in France for determining the best conditions, with respect to economy of power, under which machines may be constructed and worked. The sagacity of Watt led him to appreciate the importance of a dynamometrical machine, and he constructed his *indicator* for determining the work performed by the steam on the piston of a steam-engine during any single stroke. Prony's Friction-Break measured the work by which a shaft was driven when all other work was thrown off it. In the later constructions, however, the object has been to determine the work transmitted to the whole or any part of a machine, not for a single stroke of the piston, but continuously through any given period, and that without absorbing the whole work to be measured as the friction-break does, but while the machine is performing its usual work. Dynamometers of this kind have been contrived almost entirely by French engineers, and an account of them will be found in the 5th edition of Col. Morin's 'Aide-Mémoire de Mécanique Pratique,' and we may also refer to the 'Leçons de Mécanique Pratique,' of the same author. A good concise statement of the principles of these instruments is given in Nichol's 'Cyclopædia of the Physical Sciences,' 1857, and a detailed description of the dynamometer as originally invented by General Poncelet, and constructed under the direction of Colonel Morin, is given in Tomlinson's 'Cyclopædia of Useful Arts,' Introduction, p. clii.

In the Great Exhibition of 1851, the Jury of Class V. (Machines for Direct Use,) were assisted by Morin's Dynamometer in examining and reporting upon a number of machines exhibited, in which the same object was sought to be attained by various modifications and combinations of similar parts. There were several kinds of dynamometers exhibited, such as the *Dynamomètre de Rotation* for determining the work transmitted by a revolving shaft. There was also a dynamometer for determining the manual labour of driving the handle of a pump or crank: also a dynamometer for registering the work of the steam on the piston of an engine, through any number of strokes; this was constructed on the principle of the constant indicator [Indicator] made for the British Association of Science, and described in their Report for 1841.

The principle upon which an efficient dynamometer depends may be briefly stated: We may regard *force* as something instantaneous; or changing, or beginning, or ceasing at any moment; and *work*, as the operation of forces through spaces of time. Thus, if a body be pulled along a level road, force is exerted every moment, and if we pull another body with half the force over twice the distance, the same amount of work will have been performed. Work then depends on the force applied, and the space through which a body subjected to the force moves, and an efficient dynamometer measures the work in any case of resistance overcome and motion produced. The work will be measured by the product of the force (if kept uniformly acting) into the space through which it acts, and the instrument must measure both these quantities—the force and the space.

The original dynamometer simply determined the value of the force as in the instrument invented by Grahame and improved by Desaguliers, for ascertaining the relative strength of an individual at different periods of life and in different states of health. It consisted of a steel yard mounted in a wooden frame, and the strength of an individual was measured by acting on the short end of the lever, so as to produce equilibrium, and the position of the weight on the long arm served as a measure. An instrument by Leroy consisted of a metal tube 10 or 12 inches in length placed vertically on a foot, like that of a candlestick, and containing a spiral spring, and above it a graduated shank terminating in a globe. The shank, together with the spring, retreated in the tube in proportion to the weight acting upon it, and thus pointed out in degrees the strength of the person who pressed on the ball with his hand. Regnier's dynamometer consists of a steel spring bent into the form of an ellipse, and furnished with a semicircular plate of brass for receiving the scales or graduated arcs; these are fastened to one limb of the spring by means of a piece of steel, while to the other limb is attached a small steel support with a cleft at its upper extremity for receiving a small copper lever, which gives motion to the index needle on the scale. The scale is subdivided by hanging known weights to one of the extremities of the spring. Any force acting in the direction of the longer axis of the ellipse tends to flatten it, and giving motion to the lever, the needle moves over the scale, and shows the amount of force exerted. In trying the strength of the human body, the feet are placed in a kind of rack, to which one end of the dynamometer is attached, while the other end is furnished with a double handle, and the person under trial exerts the strength of the reins of his body in compressing the ellipse, the amount of force exerted being shown by the index. In determining the strength of the hands or the muscular force of the arms, the person holds the two sides of the spring nearest to the centre, and exerts his force in flattening the ellipse. In ascertaining the strength of animals the instrument is attached to a fixed obstacle, and the animal is yoked to the other extremity. [Animal Strength.] There are various other forms of dynamometer of this kind for determining simply the value of the force, without reference to the space through which it acts, and this would be sufficient if the force were constant, for all that would be necessary would be to measure the whole space and the one force; but as working forces are by no means constant, but are subject to frequent variations during the times when it is required to measure the work, we must take the small spaces in which the forces are tolerably constant, and multiply them by the forces which act as they move through these spaces, and by summing up the amounts of work contained in each, arrive at the total value.

We shall be able to understand how both results are obtained by the following detailed description of Morin's dynamometer. When applied to measure the mechanical force transmitted by a wheel or pulley intervening between a source of power and the machine which is to be tested, the form of the instrument is that represented in *fig.* 1 (*figs.* 2 and 3 being parts of the same instrument in different points of view), in which A is a stout axle of iron, turning freely in its bearings, and carrying a pulley or drum C. This pulley is keyed to the axle, and turns with it, while a second pulley D, is placed on the same axle, but is not fixed or connected therewith, except by means of the spring E. One end of this spring is attached to the axle, while the other is held firmly by two cheeks projecting from the side of the loose pulley D. Now it will be evident that if any resistance act on the pulley C, to prevent it from rotating, and a force be applied to D to overcome such resistance, the force could only act on C, by means of the spring E, which would be bent until its resilient tendency became just equal to the resistance acting upon C. The pulley D not being connected with the axle, except through the spring E, transmits force only by the flexure of the spring, so that if the resistance on C were continuous, such as would arise from C being made to drive a machine, and the

Fig. 1.

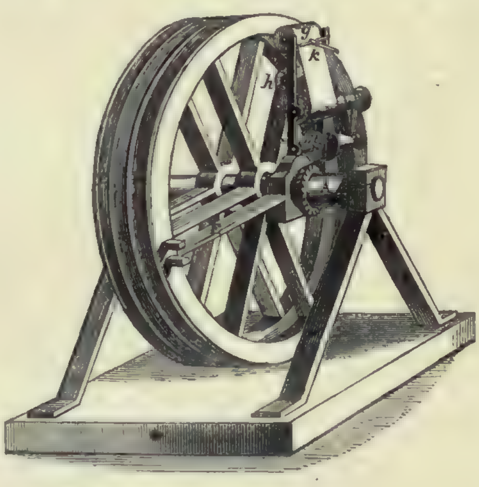


Fig. 2.

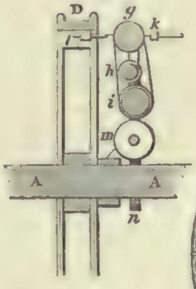

Fig. 3.

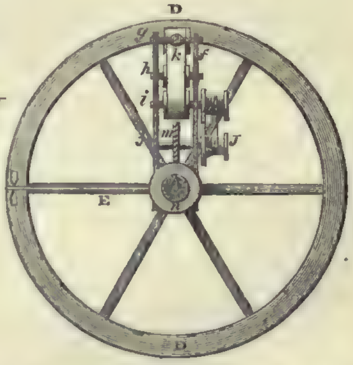


power used to set such machine in motion were applied to D, the spring would maintain a flexure corresponding to the resistance operating on C, and as this resistance varied from one moment to another, so would the flexure of the spring vary to accommodate itself to the working force which was actually passing through the dynamometer. Now, if means were contrived for accurately recording the varying flexures of the spring, we should have a complete indication of the varying power expended during any given time, during which the machine to be examined was under trial. To accomplish this, there is attached to the boss which holds the heel of the spring E, a frame-work *f*, which supports a series of roller *g h i*, a fusee J, and a pencil-holder *k*, while on the edge of the pulley D is a second pencil-holder *l*. In using the dynamometer a long ribbon of paper is wound on the roller *h*, and its outer end being carried over the roller *g* is made fast to *i*. The roller *i* is driven by a string passing from it over the fusee J, which bears on its axis a wheel *m*, in gear with another wheel *n*, situated on the axis A. It will be seen that when by the revolution of the dynamometer axis the wheel *m* is turned, the string will gradually wind upon the fusee J, and the paper will be drawn from the roller *h* over *g*, and be coiled upon *i*. The use of the fusee and string is to give a uniform rate of motion to the paper, notwithstanding the continually increasing diameter of the cylinder *i*, upon which it is being wound. The two spring pencils, *k* and *l*, are so adjusted that their points may press lightly on the paper-ribbon, and so long as the spring E remains unbent, the pencil points are exactly opposite to each other, and they trace only a single line on the paper. The teeth of the wheels *m* and *n* are cut slantingly, so that one will drive the other when placed in planes perpendicular to one another. These details being understood, let the dynamometer be set in action, and the spring E being more or less bent, the pencil-point *l* will be carried to the right or left of *k*, and as the paper is drawn under these pencil points by the action of the string winding upon the fusee J, the pencil *k* on the frame *f* continues to trace a straight line on the paper, while the other pencil *l* attached to the wheel, traces a curved line at distances from the straight line varying exactly as the flexure of the spring, and therefore exactly as the driving force transmitted by the dynamometer varies. There is a contrivance by which the observer can in an instant, engage or let free the toothed wheel *n*, so as to make it drive the other wheel *m*, which gears into it, or when let free the two wheels are simply carried round by the axis, without any relative motion. The observer then allows the paper to move during a given period, which may comprise a certain number of seconds, or a given number of revolutions of the wheel, or a certain number of strokes of a steam-engine. When the experiment has been made the machine is stopped, and the paper unwound. Now it is evident that the lengths of the lines traced by the pencil points bear a certain definite ratio to the space through which the circumference of the pulleys has moved; that is, the space through which the driving force has acted; while the distance of the two lines asunder, bears at every moment, a definite proportion to the intensity of the force which has been passing through the machine. The first of these is the measure of the abscissa of the curve traced, while the ordinate of the curve drawn at any part, represents the force acting at the corresponding moment of the experiment. Hence the area of the curve gives the product of the amount of force acting continually by the space through which it acts; that is to say, it gives the exact quantity of *work* which has passed through the dynamometer into the machine under examination. A corresponding observation having been made of the useful effect yielded during the same period, such as the number of pounds of water raised to a given height, an exact measure is obtained of the ratio of these two results, and the *duty* of the machine under examination is accurately determined.

There is another mode of registration, in which the wheel *n*, instead of driving a fusee is made to turn a small plane disk covered with hard leather. The edge of a small wheel presses lightly on this disk, and attached to the axis of the wheel is a registering train like that of a gas meter. The leather disk is attached to the frame *f*, and the steel wheel to the pulley D. The wheel is so adjusted that when the spring is not bent, the edge of the wheel shall press exactly on the centre of the disk, so that in this position the disk, when driven by the wheel *n*, has no tendency to turn the steel wheel; but when the spring is bent, the steel wheel is moved from the centre of the disk towards the circumference, and the friction thus produced between its edge and the surface of the disk causes the steel wheel to be driven at a greater or less speed, according to the relation between its own diameter and the diameter of that circle on the disk on which its edge may happen to be pressing. In this way the extent of rotation of the steel wheel is a measure of the product of the intensity of the acting force by the space through which it acts, and this being registered during any given period, gives one of the values required for the determination of the *duty* sought.

This apparatus is remarkably accurate in its results: it can be readily applied to any machine, so as to furnish the most valuable information both to the maker and to the employer of machinery. Every set of observations made with this dynamometer furnishes a manufacturing *constant* of great value in determining the cost of production under widely different circumstances. The instrument has been used for determining the power transmitted by machinery from steam-engines and water-wheels, and also for ascertaining the value of manual labour as applied to the working of pumps and driving machinery by cranks. It has also been applied to estimate the traction of horses; and every effort of a team through successive days of labour has been measured and recorded, and the work expended on such efforts numerically estimated. In comparing the various modifications of machines, some surprising differences in the results have been attained, showing how very important it is that the use of this instrument should be more widely extended. The special circumstances of each case may require modifications in its form, and in measuring forces of high intensities additional springs may be required in the other sides of the boss, and connected with the pulley D. In the Great Exhibition of 1851 were various forms of dynamometer, some of which are noticed in the 'Jury Report,' Class X., and also Class V.

DYSENTERY (Δυσεντερία, *dysenteria*, from δύς, *with difficulty*, and ἔντερον, *intestine*; *difficultas intestinorum*, *bloody flux*), a disease in which there is difficulty and pain in passing the stools, which consist of mucus and blood, containing little or no fæculent matter, and generally attended with fever. The desire to evacuate the bowels is frequent and urgent; but the effort is accompanied with severe pain, and is often altogether ineffectual, constituting the affection called tenesmus. What scanty stools are passed consist, as has been stated, of mucus mixed with blood, or of pure blood in considerable quantity; and if any fæculent matter be present, it is commonly in the form of round and hard balls called scybalæ. There is always griping pain in the abdomen. More or less fever is invariably present. The seat of the disease is chiefly in the minute glands of the mucous membrane of the large intestines, and is essentially of an inflammatory character.

The forms of this disease, the causes which produce it, the circumstances under which it prevails, the pathological conditions on which its essential characters depend, and its degree of intensity, are infinitely various; and these modifying influences cause it to assume at different seasons, in different climates, and in different constitutions, the most diversified aspects. It is sometimes a primary, sometimes a consecutive, and sometimes a symptomatic disease. It is now sporadic, now endemic, and occasionally both endemic and epidemic. It is sometimes inflammatory and sthenic, at other times typhoid and asthenic, at one time acute, and at another chronic. These differences are attended with essential differences in the nature of the disease, which not only communicate to it different external aspects, dependent on different internal conditions, but which require totally different remedies.

This disease has been at all times one of the great scourges of our fleets and armies. It occurs equally in hot and temperate climates, and seems to depend more on irregularities of diet and habit than on climate. "During the Peninsular war, the first Burmese war, and the late war with Russia, dysentery was one of the most prevalent and fatal diseases which reduced the strength of the armies."

In the acute form of dysentery, when purely inflammatory, and when mild in character, constipation commonly precedes for some days the attack of diarrhœa. The liquid and frequent stools which at length succeed to this state of constipation soon become streaked with blood; the griping pains which accompany the evacuations, and the straining and tenesmus which follow them, are often attended with distinct chills. The stools may be from eight or ten to sixteen or twenty in the twenty-four hours. The pulse is commonly quick and small, the tongue loaded, and the appetite little impaired.

When the attack is more severe, it is generally attended at the very commencement with diarrhœa, often accompanied with nausea and vomiting, quickly succeeded by scanty, mucous, or gelatinous stools, streaked with blood, preceded by tormina, and followed by tenesmus. The pain in the course of the large intestines may be either severe, or it may not be urgent, but rather a sense of heat and aching than acute pain. Pain, however, is always induced by full pressure over the tract of the colon; and if, in any particular part of this tract, there be urgent pain, some degree of fulness may generally be perceived there. The progress of the disease is indicated by the increasing severity of all the symptoms, and more especially by the increasing frequency of the stools, by the increasing tormina and tenesmus, and the augmentation of the general febrile symptoms. It is not uncommon for from twenty to forty efforts at stool to be made in the twenty-four hours, with the effect of passing only a very small quantity of mucous and blood. In all cases the evacuations are exceedingly offensive; in the worst they are of a cadaverous odour, and the clots of blood are sometimes mixed with pieces of coagulated lymph or fibrin.

In hot climates the disease is still more intense. The heat, the tormina, and the tenesmus, are more urgent and distressing; the thirst becomes excessive, the urine scanty or altogether suppressed, the stools slimy, streaked with blood, and attended with *prolapsus ani*, or watery and ichorous, "resembling the washings of raw beef, in which float particles or even large shreds of coagulable lymph, thrown off from the acutely-inflamed surface." In these cases the prostration of strength is extreme, and is increased by most distressing and exhausting vomiting. When, as sometimes happens in this form of the disease, portions of the mucous coat of the intestine slough away, the countenance of the patient is sunk and cadaverous, and the odour of the stools, and in some degree, indeed, of the whole body, is putrid.

In the asthenic form of dysentery, the tormina, tenesmus, and mucous and bloody stools are attended with great depression of all the organic functions, and extreme prostration of strength. The local dysenteric symptoms, exceedingly urgent from the commencement, are rapidly followed by fever of a low nervous or typhoid type. This form of the disease often prevails as an epidemic; and under circumstances favourable to their accumulation and concentration, exhalations from the stools of the sick seem capable of producing dysentery in persons directly exposed to them, previously in a state of sound health.

Dr. Aitken, who saw this disease in the Crimea, says, "It is the mucous membrane of the great intestine, and especially of the rectum and lower portion of the colon, which is the seat of the characteristic lesions in dysentery." These lesions are frequently attended with an exudative process, which involves the whole mucous membrane, although in a number of cases only the solitary and tubular glands are involved. The following are the morbid conditions of the intestine observed by Dr. Aitken. 1. Forms of exudation obvious on the surface of the mucous membrane of the rectum and colon. 2. Forms of exudation not obvious to the unaided eye, but which were seen in all the cases examined by the microscope, to fill the mucous tubular follicles of the large intestine. 3. Forms of exudation obvious to the eye and demonstrable by microscopic examination, as being developed in the solitary vesicular glands of the large intestine. 4. Changes in the exuded material which tend first towards its organisation and subsequently to its destruction and removal by ulceration. 5. Ulcerative changes in the tissues of the mucous membrane itself. 6. Similar dysenteric lesions extending into the small intestines." In chronic cases the exuded matter is either thrown off or it becomes organised, and subject to the ulcerative process in the same manner as the mucous membrane. In all cases the solitary and tubular glands appear to be first attacked.

The duration of dysentery is as various as its types. It may prove fatal in a few days or hours, or last for weeks and even months, and ultimately destroy life by inflammation and gangrene of the bowels. In some cases the disease ceases spontaneously, the frequency of the stools, the griping and the tenesmus gradually diminishing, while natural stools return; but in other cases, the disease, with moderate symptoms, continues long, and ends in protracted and exhausting diarrhœa.

The causes which predispose to dysentery appear to be long-continued exposure to a high temperature, or alternations of heat and cold; hence the disease is generally most prevalent in summer or autumn, after considerable heats have prevailed for some time, and especially after very warm and at the same time very dry states of the weather. All observation and experience show that a powerful predisposition to the disease is formed by the habitual use of a high and stimulating diet, and especially by indulgence in spirituous liquors, by excessive fatigue, by exposure to night air, by salt diet, and by all causes which enfeeble the constitution in general, at the same time that they over excite the alimentary canal in particular.

The exciting causes are long-continued exposure to intense heat, or to sudden and great alternations from heat to cold; exhalations from vegetable and animal matters in a state of decomposition, as from marsh, stagnant, river or sea water, from animalculæ and minute insects, or from the flesh of deceased animals; noxious exhalations from the bodies of persons crowded together in close and confined situations, and more especially, as would appear, from the discharges from the bowels of persons labouring under dysentery; scanty and bad food, consisting more especially of vegetable or animal matter in a state of decay, as tainted meat, stale fish, unwholesome bread, unripe rice, rye, and impure water.

In the acute form of dysentery, when the fever is high, the pain intense, and the inflammation active, blood-letting from the arm has been recommended, and also the local abstraction of blood by leeching or cupping. The employment of purgative remedies in dysentery requires the greatest discrimination and caution. If the colon be distended with feculent matter which it cannot discharge, no remedies will succeed until this accumulation is removed; if, on the contrary, there have been already frequent and copious discharges of feculent matter, the administration of purgatives should be avoided. The practitioner should therefore carefully examine the state of the bowels with regard to their fulness or emptiness of fæcal matter, and their actual state in this respect can almost always be ascertained with a great degree of certainty if due pains be taken to discover it. If there be reason to suppose that there is any accumulation of fæces, the mildest purgatives should be given, of which the best is castor oil, and this should be cautiously repeated until the irritating matter is wholly removed. Great relief is at the same time afforded to the distressing tormina and tenesmus by emollient and opiate enemas injected in very small quantities. After the subdual of the inflammatory state by blood-letting, and the evacuation of the accumulated fæces by mild purgatives, the great object is to soothe the irritated membrane by opiates, on the judicious employment of which, and the skilful combination and alternation of this class of remedies with mild purgatives and astringents, the successful treatment of ordinary dysentery mainly depends. The asthenic forms with typhoid symptoms need a guarded yet active treatment, nearly the same as that which is proper to typhus fever with abdominal affection. [FEVER.]

DYSLYSINE. [CHOLIC ACID.]

DYSLYTE. A nitrogenous product not yet analysed, obtained by the action of nitric acid upon citraconic acid. It is produced simultaneously with *eulyte*.

DYSPEPSIA (Δυσπεψία, *dyspépsia*), *Indigestion*, the difficult and imperfect conversion of the food into nutriment. Digestion is a part of the great function of nutrition; its ultimate object is to convert the aliment into blood. Between the articles taken as food and the nutrient fluid of the body—the blood, there is no obvious analogy, and there is a wide difference in nature. Hence the function of digestion consists of a succession of stages, at each of which the food undergoes a specific change. Each change is effected by a peculiar process, for the accomplishment of which a special apparatus is provided. Of these processes the chief are mastication, deglutition, chymification, chylification, and fæcation. [DIGESTION, in NAT. HIST. DIV.] The healthy condition and the natural action of every individual organ belonging to the portion of the apparatus proper to each of these processes is necessary to the sound state of the function of digestion. It is easy therefore to see by how many causes it may be disturbed; in how many different organs the source of the disturbance may have its seat, of how varied a nature the disturbance may be, and how greatly the disturbance of the digestive function may derange the other functions of the body.

In the history of the human family there is no known community of human beings in any country, and no age of human life, in which the first necessity of existence, that of taking food for the nourishment of the body, is not the cause of disease and death to great numbers, and of uneasiness, nay, sometimes even of intense pain, to far greater numbers. Why is this? Why is the digestive process more productive of suffering, disease, and death in man than in the lower animals of a similar structure, in which the function, considered in a physiological point of view, is scarcely at all less complex? The correct answer to this question would include a clear account of the causes of dyspepsia, and would suggest the appropriate remedies for the disease.

Digestion being an organic function, when this function is healthfully performed, for reasons which have been fully developed, it is unattended with consciousness. The first effect of the disturbance of this function is to render the patient not only conscious, but painfully conscious, that he has a stomach. A sense of nausea, sometimes, when the affection is severe, even vomiting, an obscure feeling of uneasiness, fulness, distension, weight in the region of the stomach, occasionally amounting to pain, and even severe pain, flatulence, eructation, a sensation of sinking, and lastly, a loss of appetite, constitute the train of uneasy sensations which, coming on after the reception of food, indicate disordered digestion, and which take the place of the feelings of refreshment and exhilaration which result from healthy digestion.

When these uneasy sensations are occasioned by a disordered state of the stomach, the disorder may consist in a derangement either of its secreting arteries, or its mucous glands, or its organic nerves, or its muscular fibres, inducing a deficient secretion of the gastric juice, a deficient secretion of mucus, a diminished or increased irritability of the muscular fibres, by which the motions of the stomach are disturbed. If the gastric juice be deficient, the first step in the digestive process cannot take place, the food cannot be dissolved; if the mucus be excessive, the contact of the gastric juice with the food may be prevented: if the muscular fibres of the stomach are torpid or too irritable, the food may be detained too long or too short a time in the stomach.

The causes of dyspepsia are either those which act directly and immediately upon the stomach itself, or those which act upon the whole body or upon particular parts of it, but which still affect the stomach principally and almost solely.

Of the first kind are noxious, irritating, and indigestible substances taken into the stomach as articles of food or drink, such as tainted meat, decayed vegetables, unripe fruit, very acid matters, ardent spirits, &c.; and even wholesome food taken too frequently or in too large a quantity, especially when its nature is very nutritious, as when it consists principally of animal matter, or when a large quantity of nutriment is presented to the stomach in a very concentrated form, or is rendered too stimulating by being highly seasoned; the abuse of fermented and spirituous liquors, which is one of the most frequent causes of dyspepsia in its severest and most fatal forms; and large quantities of fluids, habitually taken at too high a temperature, as very hot tea, coffee, or soup.

Of the second kind, or the causes which act upon the whole body or upon particular parts and functions of it, are—want of pure air; hence the frequency of dyspepsia in large and crowded cities, and more especially in narrow and confined lanes and alleys, in the dirty and ill-ventilated houses of the poor. Want of exercise: from physical inactivity all the organs of the body languish, but the stomach first and most. Intense study or close application to business too long continued, implying both want of air and want of exercise. Mental emotion, more especially the depressing passions, fear, grief, vexation, disappointment, anxiety, and hope deferred. Exposure to the influence of cold and moisture. In persons with weak stomachs and delicate skins, a cold damp day, more especially suddenly succeeding a hot day, often produces a severe attack of dyspepsia. Hence it is that dyspeptic complaints are so prevalent when cold and damp weather first sets in. Cold is a sedative to the nervous system, as heat is an excitant; and the depressing effects of cold seem to be peculiarly manifested in the nerves of the stomach. Excessive discharges from the body, as flooding, leucorrhœa, large bleedings from the arm, profuse and long-continued sweating, and above all protracted suckling. It is a common practice among the poor in this country to suckle their children too long. A feeble woman is often seen with a strong child at her breast a year and a-half or two years old. The effect upon the constitution of the mother is most pernicious. Emaciation, sharpness of the features, with a peculiar expression in the countenance of languor and exhaustion, a sense of sinking at the pit of the stomach, dimness of sight, giddiness, spectra of different kinds dancing before the eyes, headache, with a small, quick, and sometimes almost imperceptible pulse, and total loss of appetite, are the peculiar characters of this variety of dyspepsia.

The state of dyspepsia is most frequently a state merely of disordered function, without any appreciable change of structure in any of the tissues of the stomach. But all the symptoms of dyspepsia are produced in their intensest degree when they arise from some organic disease of the stomach. Of these the most frequent is inflammation of its mucous coat. This inflammation may be either acute or subacute. When acute, the nature of the malady is indicated by characters so striking that it cannot be overlooked; but the subacute form often exists for a long period quite unsuspected, producing violent and obstinate dyspepsia, which is often greatly aggravated by the remedies employed to remove the complaint. The diagnostic sign of this form of the disease is tenderness on pressure in the epigastric region. In scirrhus of the pylorus and ulceration of the mucous glands of the stomach, organic disease not of unfrequent occurrence, there is superadded to the ordinary signs of dyspepsia a peculiar train of symptoms scarcely to be overlooked or mistaken.

But dyspepsia is often the result of disease situated not in the stomach, but in some other organ. The stomach has been justly called the centre of sympathies, and there is scarcely any disorder of the body which does not affect the functions of the stomach in a greater or less degree. The organs the diseases of which are most apt to produce disorder of the stomach, are the liver, the spleen, the uterus, the kidney, the bronchi, and the skin. In this secondary form of dyspepsia, the disease cannot be removed unless the seat of the primary affection, and the true nature of that affection, be ascertained.

The stomach is the organ in which chymification is effected. Chylification is accomplished in the duodenum, and completed in the jejunum, ilium, and mesenteric glands; and the highly important part of the digestive process, that which consists in eliminating and carrying out of the system the non-nutrient portion of the aliment, is performed by the large intestines. Each of these organs may be the primary seat of disease, giving rise to the ordinary symptoms of dyspepsia; but to these there will generally be superadded peculiar signs pointing out the real seat of the malady, signs almost always to be observed if carefully looked for, and the detection of which is of the utmost importance in the treatment of the disease.

The indications of cure are to avoid or remove the remote causes, to remove the symptoms which especially contribute to aggravate and continue the disease, and to restore the healthy tone of the disordered organs. There is no drug, no class of medicines, no one mode of treatment capable of removing dyspepsia when present, or of preventing its recurrence. This can only be done by a careful study of the exact cause of the disease in every individual case, and the precise seat and nature of the affection. The mode of treatment must be modified in strict accordance with these circumstances; and no mode of treatment will be attended with success of which the appropriate regulation of the diet and exercise does not form an essential part. [STOMACH, DISEASES OF.]

E

E occupies the fifth place in the Hebrew alphabet and those derived from it. The vowels, when arranged according to their physical affinity, would lie in the series *i*, *e*, *a*, *o*, *u* [ALPHABET], and accordingly the vowel *e* is frequently interchanged with its neighbours *i* and *a*. It is also under special circumstancs occasionally convertible with *o* and *u*.

1. *E* is interchanged with *i*. Thus in Latin the old datives *heri*, *mani*, *ruri*, *musai*, afterwards took the forms *here*, *mane*, *rure*, *musae*; and the words *magis*, *videris*, *tristis*, when they appeared without an *s*, were written *mage*, *videre*, *triste*. The same interchange appears in the declension of the adjective *is*, *ea*, *id*, and the conjugation of the verbs *eo* and *queo*.

2. *E* in Latin often corresponds to *oi* in French. Thus many Latin infinitives in *ere* reappear in French with the termination *oir*, as *habere*, *debere*; *avoir*, *devoir*. The Latin past imperfect has the suffix *eba*, which passed through the forms *eva* and *ea* to *oie* and *oi*. Thus from *habebam* were deduced *aveva*, *avea*, *avoie*, and lastly *avois* or *avais*. This final *s*, so far as regards the first person, does not appear in the oldest forms of the French language. Other instances of the change of *o* into *oi* may be seen in the Latin adjectives and other words in *ensis* or *esis*, which in French have the suffix *ois*, *Viennensis*, *Viennois*; *mensis*, *mois*.

3. *E* Latin into *ie* French, as *mel*, *bene*, *ped-*; *miel*, *bien*, *pied*.

4. *E* into *a*. This is well marked in the dialects of the Greek *σοφιη*, Ionic; *σοφια*, Doric, &c. Hence the Latins have often an *a* where the common dialect of the Greek had *e*, as *μηχανη*, *πληγη*; Lat. *machina*, *plaga*. Both forms often coexist in Latin, as *tristitia-* and *tristitie-*. The *a* is often changed into *e* in Latin, if a prefix is added, particularly if two consonants follow the vowel, as *factus*, *confectus*; *pars*, *expers*; *castus*, *incestus*; *ars*, *iners*.

5. *E* into *o*. Especially in Greek, when a strong vowel follows, as *λεγω*, *λογος*; *νεμω*, *νομος*. The Latin language prefers an *o*, as *ἐμεω*, *vomo*; *πεπτω*, *coquo*; *νεος*, *novus*; *επι*, *ob*. This change is particularly common in words beginning with a *w*, or with what was pronounced as a *w*, the Latin *v*. Thus *vester*, *verto*, *veto*, were once written *voster*, *vorto*, *voto*. Even in our own language *worm* (vermis, Lat.), and *work* (*ἐργον*, Gr.), are now pronounced as if written with an *e*. The Greek even interchanges a long *o* with a long *e* as *πατηρ*, *ἀπατωρ*, *εὐπατωρ*; and so too in Latin we have *Anio Aniēnis*.

6. A short *e* often gives place in Latin to a short *u* when followed by one of the liquids *l*, *n*, *m*, as in *Siculus*, (Gk. *Σικελος*) *perculsus* (*percello*), *tabula* (Germ. *tafel*), *decumus* (*decem*), *contumax* (*temno*), *funda* (*σφενδόνη*), *faciundus* (*faciendus*) *euntem*.

EAGLE, CONSTELLATION. [AQUILA.]

EAGLE, Roman Standard. The eagle, as a symbol of empire, is often seen on ancient coins and medals, and on none more frequently than on those of the Ptolemies of Egypt and the Seleucidæ of Syria. As an ensign or standard, borne upon a spear, it was used by the Persians in the time of the younger Cyrus. (Xenoph., 'Anab.' i. 10.)

Pliny ('Hist. Nat.' li. x., c. 4, edit. Hardouin, tom. i., p. 549) says that, till the time of C. Marius, the Romans used five different animals for standards,—the wolf, the minotaur, the horse, the boar, and the eagle,—but that in Marius's second consulate they adopted the eagle as the sole ensign for their legions.

The eagle used by the Romans as a standard was of gold or silver: the latter metal, we are told by Pliny, was most frequently used, as the more glittering, and of course more readily seen. It was borne, like the Persian eagle, on the summit of a spear, and was of the size of a pigeon, with its wings displayed. It sometimes rested upon a cross-bar on the top of the spear, and sometimes upon shields piled up. On the reverses of some of the coins of Augustus and Galba, in second brass, the legionary eagle is represented holding the thunderbolt in its talons. The small size of the eagle often contributed to its concealment, when the legion to which it belonged was defeated. The name of the legion was usually engraved upon it. Tacitus, in his 'Annals,' l. i. 60, relates the finding of the eagle of the nineteenth legion by Germanicus, which had been lost in the massacre of Varus.

Cicero ('Catilin.' i., c. 24) says that Catiline had a silver eagle in his house as his titular divinity, which was also his standard in war.

A Roman eagle in steel, found at Silchester, presumed to have been a legionary eagle, was exhibited to the Society of Antiquaries in 1788 by the then bishop of Carlisle.

The reader will see a great deal of learning displayed upon this and the standard of the cohorts in M. Le Beau's 'Quatorzième Mémoire sur la Legion Romaine; Des Enseignes.' Mem. de l'Académie des Inscript. tom. xxxv., 4to, Par. 1770, pp. 277–308.

The eagle has also been adopted as the standard in the modern French army. It is borne perched at rest on a small base at the top of the banner-staff. Austria bears a double-headed eagle on her banners; and Prussia and Russia have taken the eagle as their national symbol. The United States of America use also the eagle as the national emblem, as well as for the designation of a gold coin of the value of 43*s.* 8*d.*, or 10 dollars.

EAGRE. [BORE.]

EAR-RING; a ring hung from a hole, perforated for that purpose through the ear, sometimes set with pendant jewels, pearls, or other precious stones. The word is Anglo-Saxon, *ear-hring*. Ornaments of this sort, large or small, have been worn in almost all countries by women, from the earliest ages; but more rarely by the men. In ancient Egyptian paintings females are represented with large circular ear-rings; but no male figures, except of captives, wear them. In Assyrian sculpture, on the other hand, in which few native female figures occur, all the males of rank from the great king downwards wear large ear-pendants. Botta (plate 161) has figured several of them. Among Oriental nations generally the ear-ring appears always to have been a customary ornament with both sexes. Among the Greeks and Romans it was confined exclusively to the men. Homer makes Hera, when adorning herself so as to appear most fascinating in the eyes of Zeus, place in her ear-tips three-gemmed ear-rings. ('Iliad,' xiv. 182.) Several of the most beautiful Greek female statues have the ears pierced for the reception of ear-rings, which were no doubt of gold or gems. In the Latin of the middle age ear-rings are termed *pendentes*, from the more common form of the ornaments usually attached to the ring itself. Ear-pendants have been occasionally found in British and Saxon barrows in various parts of England.

EAR-TRUMPET, a curved tube employed to aid defective hearing. The rays of sound, proceeding from any source, enter the tube nearly parallel, and its inner surface is so curved that, after one or more reflections, they *converge* upon the membrane of the tympanum, and thus act with increased force.

In early notices of acoustic instruments there is some difficulty in distinguishing such as were intended to be applied to the ear, to assist in collecting sound, from such as were employed in aid of the voice, to enable a speaker to produce articulate sounds in such a manner as to insure their transmission to a considerable distance. [SPEAKING TRUMPET.] To a certain extent, indeed, such instruments may be employed for either purpose, some speaking-trumpets being so formed that, if applied to the ear, they would act as hearing- or ear-trumpets.

The common ear-trumpet is a conical tube of metal, the larger end of which expands like the mouth of a trumpet, while the smaller is so shaped as to enter the ear, and conduct the vibrations of sound collected at the wide end direct to the membrane of the tympanum. The smaller end is frequently curved, in order that it may be applied properly to the ear while the mouth is directed forwards to receive sounds from a speaker in front of the person using it. For the sake of portability, ear-trumpets are frequently made in two, three, or more portions, sliding within one another, somewhat in the same manner as the tubes of an opera-glass.

Various other instruments, of doubtful value, are more or less employed in aid of defective hearing: among these may be mentioned, the *auricle*, a small shell-like instrument, formed of gold, and worn in the ear, so that nothing but the expanded mouth is visible; *ear-cornets*, which are small instruments, made of various shapes and sizes, somewhat resembling a French horn or a musical trumpet in appearance, applied to the ears and held in their place by slender springs; *speaking* or *conversation tubes*, which are flexible elastic tubes of India-rubber and silk, kept open by spiral wire springs, and terminating at one end in an ear-piece, and at the other in an open bell-shaped vessel, which is held before the mouth of the speaker; and *table sonifers*, which consist of a revolving trumpet-shaped cowl mounted on a pedestal, which may be placed upon a table, so as to be turned towards any part of the room where conversation may be going on, and of communicating the sound through a flexible tube to the ear of the deaf person. When flexible tubes are employed for such a purpose, their effect is increased by making them of a tapered or conical shape. An ingenious instrument of the ear-trumpet kind is made in the form of a walking-stick. Another, which is held so as to reflect sound into the ear, is styled the *ear-conch*, and may be termed an auxiliary ear: it is formed of plated metal. The commoner kinds of acoustic instruments are made of tin-plate, japanned; but the better sorts are sometimes formed of silver, or of gong-metal, which is supposed by some to be the best metal for the purpose.

Hebert ('Engineer's and Mechanic's Encyclopædia,' vol. i., p. 463) quotes an opinion from Dr. Morrison, of Aberdeen, that that end of an ear-trumpet which is applied to the ear should not be made so small as to enter the ear, but should be large enough to include the whole of the external ear; for that gentleman, having been deaf for many years, experienced no relief from ordinary ear-trumpets, but found one which he had made of block-tin, on the proposed plan, to succeed.

EARL. The title of count or earl, in Latin *comes*, is the most ancient and widely spread of the subordinate or subject titles. This dignity exists under various names in almost every country in Europe. By the English it is called earl, a name derived to us from the ealderman of the Anglo-Saxons and the eorle of the Danes. By the French it is called *comte;* by the Spaniards *conde;* and by the Germans *graf*, under which generic title are included several distinct degrees of rank, —landgraves, or counts of provinces; palagraves, or counts palatine, of which there are two sorts; markgraves, or counts of marches, or frontiers (whence marchio, or marquess); burghgraves, or counts of cities; counts of the empire; counts of territories; and several others. [Count; Baron.]

After the battle of Hastings, William the Conqueror recompensed his followers with grants of the lands of the Saxon nobles who had fallen in the battle, to be held of himself as strict feuds; and having annexed the feudal title of earl to the counties of the Saxon earls (with whom the title was only official), he granted them to his principal captains.

These earldoms were of three kinds, all of which were by tenure. The first and highest was where the dignity was annexed to the seisin or possession of a whole county, with *jura regalia*. In this case the county became a county palatine, or principality, and the person created earl of it acquired royal jurisdiction and seigniory. In short, a county palatine was a perfect feudal kingdom in itself, but held of a superior lord. The counties of Chester, Pembroke, Hexham, and Lancaster, and the bishopric of Durham, have, at different times, been made counties palatine; but it does not appear that the title of earl palatine was given to the most ancient and distinguished of them—namely, the earl of Chester—before the time of Henry II., surnamed Fitz-Empress, when the title of palatine was probably introduced from the empire. The earls of Chester created barons and held parliaments, and had their justiciaries, chancellors, and barons of their exchequer. This county palatine reverted to the crown in the reign of Henry III. The second kind of earls were those whom the king created earls of a county, with civil and criminal jurisdiction, with a grant of the third part of the profits of the county court, but without giving them actual seisin of the county. The third kind was where the king erected a large tract of land into a county, and granted it with civil and criminal jurisdiction to be held *per servitium unius comitatûs*.

Under the early Norman kings, all earls, as well as barons, held their titles by the tenure of their counties and baronies; and the grant, or even purchase, with the licence of the sovereign of an earldom or a barony, would confer the title on the grantee or purchaser; but with the solitary exception of the earldom of Arundel, earldoms by tenure have long since disappeared, and in late times the title has been conferred by letters patent under the great seal. Earls have now no local jurisdiction, power, or revenue, as a consequence of their title, which is no longer confined to the names of counties or even of places; for several earls, as Earl Spencer, Earl Grey, and others, have chosen their own names instead of local titles.

The coronet of an English earl is of gold surmounted with pearls, which are placed at the extremity of raised points or rays, placed alternately with foliage. The form of their creation, which has latterly been superseded by the creation by letters patent, was by the king's girding on the sword of the intended earl, and placing his cap and coronet on his head and his mantle on his shoulders. The king styles all earls, as well as the other ranks of the higher nobility of peerage, his cousins. An earl is entitled right honourable, and takes precedence next after marquesses, and before all viscounts and barons. When a marquess has an earldom, his eldest son is called earl by courtesy; but notwithstanding this titular rank, he is only a commoner, unless he be summoned to the House of Lords by such title. So the eldest sons of dukes are called earls where their fathers have an earldom but no marquisate, as the Duke of Norfolk, &c.

The number of English earls in the House of Lords is at present (1859) 110. Of Scotch earls there are 42, and of Irish earls 65, of whom many have seats in the House of Lords in consequence of possessing a British peerage also.

EARL MARSHAL OF ENGLAND, one of the great officers of state, who marshals and orders all great ceremonials, takes cognisance of all matters relating to honour, arms, and pedigree, and directs the proclamation of peace and war. The *curia militaris*, or court of chivalry, was formerly under his jurisdiction, and he is still the head of the heralds' office, or college of arms. Till the reign of Richard II., the possessors of this office were styled simply marshals of England; the title of earl marshal was bestowed by that king, in 1386, on Thomas Lord Mowbray, Earl of Nottingham. The office is now hereditary in the family of Howard, and is enjoyed by the Duke of Norfolk.

EARTH (Astronomy). In the language of astronomers, the earth is rarely treated as a planet. All the phenomena connected with its motion are seen in the apparent motion of the Sun, to which article we therefore refer.

EARTH, CONTROVERSY ON THE MOTION OF THE. [Motion of the Earth.]

EARTH, FIGURE OF THE. [Geodesy.]

EARTH, MEAN DENSITY OF THE. The quantity of matter which the earth contains must ultimately be our only guide to that of any other planet. The relative masses of two planets can be found by calculation of the effects which they produce upon any third body; but the mass of a planet with reference to any given substance, as water, cannot be directly determined upon any instance except our own earth. Perhaps a problem could hardly be proposed which would seem more impracticable to the ordinary reader than that of determining the mean density of the earth. It amounts to asking this:—If it were required to substitute for the earth a solid globe of the same size, *but of uniform material*, in such a manner that the absolute weight of bodies on its surface should remain the same, and the attraction of the whole on other planets remain the same—what must the material be?

Of necessity this question was started by Newton, whose system was the first in which it became of much interest. Having no means of submitting it to experiment, he made one of those sagacious guesses which, had they been collected and preserved, would alone have kept his memory alive. "Unde cum terra communis suprema quasi duplo gravior sit quam aqua, et paulo inferius in fodinis quasi triplo vel quadruplo aut etiam quintuplo gravior reperiatur: verisimile est quod copia materiæ totius in terrâ quasi quintuplo vel sextuplo major sit quam si tota ex aquâ constaret." ('Principia,' iii. 10.) That is, he judged the earth to be between five and six times as massive as the same bulk of water; which is the truth.

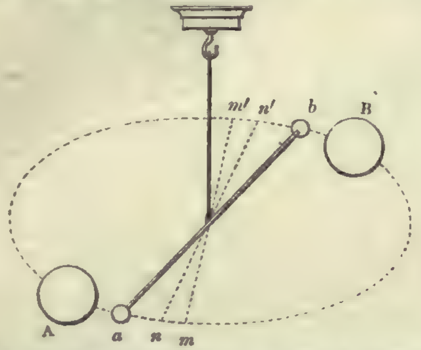
The relative masses of two planets are determined by the observation of their effects upon a third. Two preliminaries are required: first, the great assumption of the theory of gravitation, that any two particles of matter must attract one another with forces which at different distances are directly as their masses, and inversely as the squares of those distances; secondly, the mechanical consequence of this law of action, namely, that two spheres, having their centres at any given distance, attract one another in the same manner as if each were collected in its centre. Without describing the mode of arriving at such a result from observation, suppose it is ascertained that two planets, A and B, whose distances from a third are as 4 to 3, attract that third with forces which are as 7 to 2. If both planets be brought to the distance 1 from the third, the attraction of the first will be made (4 × 4, or) 16 times as great as before, and that of the second (3 × 3, or) 9 times. Consequently, the new attractions will be as 7 × 16 to 2 × 9, or as 112 to 18. But at equal distances the attractions are in the proportion of the masses; therefore these masses are as 112 to 18. Now suppose the radii of the planets to be as 3 to 2; then their solidities are as 27 to 8, and if the densities (mean) are δ and δ', the masses are as 27δ to $8\delta'$. Therefore $27\delta : 8\delta' :: 112 : 18$, or $\delta : \delta' :: 112 \times 8 : 18 \times 27 :: 896 : 486$. If then the mean density of either planet be known, that of the other can be found.

The principle of the preceding process exists in every attempt which has been made to find the mean density of the earth. The earth itself is made one of the planets; some known substance, a mountain or a ball of lead, is made the other planet. The attracted body is not a planet, but a pendulum or a plumb-line, and the effect of the mountain or ball of lead upon the plumb-line is measured, that of the earth being either measured or previously known. The actual attraction of the mountain or ball of lead being thus determined, its effect as it would be if placed at the centre of the earth can be calculated; which effect is to the effect of the earth as the mass of the mountain or ball of lead to that of the whole earth. The result of this process, as usual, is condensed into a formula, in which the mode of making the steps is lost sight of: but the above is not the less the manner in which the experiment must be explained.

The hint given by Bouguer, the experiment of Maskelyne, and those of Cavendish and Zach, have been briefly described in Attraction. Since their time two repetitions of Cavendish's experiment have been made: the first, by Dr. Reich, of Freyberg, of which an account was published in 1838; the second, by Mr. Baily, at the desire of the Astronomical Society, and at the expense of the government. ('Mem. Ast. Soc.,' vol. xiv.) The former obtained the same result as Cavendish, but the experiments were few in number; the latter obtained a result slightly differing from that of Cavendish, but in so many different ways and by so large a number of experiments, that it is impossible to doubt the superior correctness of the conclusion. We shall give such a slight general account of this process (which is substantially that of Cavendish) as our limits will admit, referring to the volume already cited for more detail: very few experiments have been either so well performed or so satisfactorily described.

A torsion pendulum (76 inches long) was provided, moving on a single or double metal wire, or on a double silk line, the mode of suspension being varied from time to time. At each end was suspended a metal or other ball; and these balls (*a* and *b*) were the principal attracted substances. The whole torsion-rod with the suspension was inclosed in a case, with a glass at one end. Large leaden balls (A and B) of about twelve inches diameter (the attraction of which on the torsion pendulum is the quantity to be measured in the experiment) were made to travel on a frame in such manner that they could quickly be brought up laterally on opposite sides of the balls, as in the diagram. We must leave out the whole account of the precautions against electricity or radiation, the manner of noting the actual position of the pendulum, &c., and confine ourselves to the principle of the experiment.

When a torsion pendulum, such as that described, is left to itself, it never is reduced to absolute rest. The instrument is so delicate that it is in continual oscillation to a small extent, and its position of rest, say *mm'* is found by taking the mean of the extreme positions on one side and the other. Even this mean position is continually shifting its direction, so that it cannot be permitted to take a series of observations and make use of them all in determining one mean place. The mode of finding the point of rest, that is of deducing it from observing the extremes of the vibration, is described in the work cited. As soon as the line of rest of the undisturbed pendulum is ascertained, and the large balls are brought into the attracting positions at A and B, on continuing the observation an immediate alteration of the line of rest is seen towards the large balls; say that it becomes *nn'*. Then the position of equilibrium of the pendulum is altered by the angle *nom*, in consequence of the approach of the balls.* The precautions taken are abundantly sufficient to assure us that the alteration is no consequence of heat, electricity, magnetism, or any of the variable accidents of matter; there is nothing to which it can be referred except that attraction which, when the earth is the agent, we know under the name of weight, and the assumption of which, as a universal property of matter, led Newton to his explanation of the planetary motions. Many of those who were content to receive Newton's hypothesis to this extent, that the planets attract each other, were staggered by the idea that every particle in the universe attracts every other. Such objectors might have here received conviction from the evidence of their own senses, which would have rendered obvious not only the attraction of the balls upon each other, but its transmission through the wood, flannel, and gilding, which it was found necessary ultimately to interpose between the attracting substances and the torsion-rod in order to destroy the effects of radiant heat.



Two observations are necessary, that of the time of oscillation of the pendulum, and that of the displacement of the line of rest which the approach of the larger balls produces. The first observation, the time, enables the observer to deduce the force of torsion, or the quantity of pressure required to produce any given displacement. And in this particular it was found that the pendulum altered its character from one quarter of an hour to another; showing that the instrument was so delicate, that circumstances of which no explanation can be given were continually altering its character. The consequence was, that at every new trial, both the time and displacement had to be scrupulously observed together, in order that to each displacement produced the proper producing attraction might be applied. The complete formula for calculating the mean density of the earth, implies,—1. The calculation of the character of the pendulum, or the amount of attraction necessary to alter its line of rest by a given quantity; 2. The determination of the attraction actually employed, namely, that of the larger balls, by means of the displacement actually observed; 3. The determination of the attraction which the larger ball would exert, if it had been at the centre of the earth, instead of at the distance † employed; 4. The number of times the whole earth would contain such a leaden ball, and its easy consequence, namely, the number of times the whole earth would contain a similar bulk of water; 5. All the necessary corrections for the attraction of the other parts of the apparatus upon the torsion pendulum.

The larger masses were leaden balls, but the smaller balls attached to the torsion pendulum were changed from time to time, and different substances were used. The following table of results will be more interesting than any description we could give in the same space. It shows the result of the experiments made after the effects of radiation were removed ‡ by additional precautions. The first column is the number of experiments made, with the small balls and mode of suspension described in the third; the second contains the mean density of the earth as deduced from that set of experiments; the third describes the small balls and mode of suspension employed; the numerals, which are fractions of an inch, representing the diameter of the suspension wire, when single, and the distance of the wires when double or *bifilar* :—

The results of individual experiments vary considerably, but it is important to observe that there is nothing which indicates that different kinds of matter attract each other according * to different laws. If the large ball of lead exerted different attractions upon particles of brass and ivory of the same weight, the effect would be to give the whole earth one mean density or another, according as the smaller ball is of brass or ivory. Now it is true that the experiments give all manner of results from 5·500 to 6·154, but on examining the results, there appears no evidence whatever of the larger balls attracting the different smaller ones differently. If such were the case, undoubtedly the mean densities obtained from different substances would be different; but though such is the case in the preceding list, and even though it would seem that the lighter balls give the larger densities, yet there is every reason to suppose that the effect is to be attributed to the alteration of the pendulum. Thus it will be seen that there is not so much difference between the results of 2-inch ivory and lead balls suspended in the same way by a single copper wire, as there is between the results of 2-inch lead balls suspended by bifilar iron wires, and the same suspended by bifilar brass wires, and also that ivory balls differently suspended give results which have differences as great as any. The mode of suspension and the effect of merely increasing the weight of the smaller balls, appear much to exceed that of applying different substances; but not according to any law. In fact, the differences are altogether of that character to which the term discordance is applied; following no settled rule, and exhibiting every appearance of as often affecting the truth by a positive as by a negative error. The first three sets, in which a brass rod alone is used, were rather a defiance to the apparatus to fail if it could, than seriously intended to help the result. Almost all the experiments were made with a light wooden torsion-rod, and comparatively heavy balls appended. The trying a brass rod by itself, that is, the attempt at obtaining a mean density by noting the attraction of the larger balls upon the torsion-rod only, was the introduction of an extreme case, to increase confidence in the more ordinary experiments.

The mean of the whole is 5·6747, and, rejecting the experiments of which the character would be *à priori* most doubtful (though it is not certain they ought to be rejected) it is reduced to 5·6604. From the experiments, by the usual rules of the theory of probabilities it is an even chance that the error of this result is within ·04. Cavendish's result was 5·48.

---

* In making the experiment the effect was usually doubled by placing the large balls first on one side of the smaller ones, and then on the other, and noting the whole of the double displacement.

† This distance of course was accurately measured.

‡ An enormous mass of experiments was made and rejected in the course of the attempts to remove singular discordances, of which no explanation could be given. The mean result of these would not have differed much from those of the more correct sets, but would, of course, have been less satisfactory. The removal of the discordances was due to the suggestion of Professor Forbes, of Edinburgh, who continued to believe they might arise from radiation long after others thought the precautions then already taken must have been sufficient to remove that source of disturbance.

* That it is not the case, is also established without a doubt by pendulum experiments.

Besides the confirmation of some of the most material points of the theory of gravitation which results from this experiment, it furnishes a presumption of the strongest kind that the earth is solid to the centre, and not, as many have supposed in every age, a hollow shell. The mean density 5½ is very much greater than that of the substances which abound at the surface. All common rocks are under 3, and nothing under the ores of the heavier metals comes up to 5½. The earth is as massive as if it were all composed of silver-ore, from the centre to the circumference, so that there must be an increase of density towards the centre. If those who think the earth to be a shell were to presume that its solidity ceased at five hundred miles below the surface, they would then be compelled to give to the terrestrial matter, one part with another, a density greater than that of mercury, in order that the whole shell, the hollow part included, might have the mean density which is found by this experiment.

Recently, Mr. Airy, the present Astronomer Royal, has determined the mean density of the earth by means of observations of the rate of oscillation of a pendulum made at the top and bottom of a coal-mine in the county of Durham. As early as the year 1826 he endeavoured, in conjunction with Dr. Whewell and the late Mr. Sheepshanks, to effect the same object by means of pendulum experiments in the Dolcoath mine in Cornwall, but the project was frustrated by local accidents; and a similar attempt in 1828 proved equally fruitless. The principal obstacle to the success of the experiments on those occasions consisted in the difficulty of comparing the clocks at the top and bottom of the mine. In more recent times the application of galvanic electricity to the transmission of signals suggested to Mr. Airy an easy method of conquering this impediment. He accordingly resolved to repeat the experiment, and chose for that purpose the Harton colliery, near South Shields, the bottom of which is no less than 1260 feet beneath the earth's surface. The application of pendulum experiments made at the earth's surface, and at some distance beneath it, to the determination of the mean density of the earth, rests on two principles of attraction, both of which were originally established by Newton. The first is, that the attraction exercised upon an external particle by a sphere of uniform density, or one consisting of concentric strata of different densities, but of uniform density throughout each stratum, is the same as if all the matter of the sphere were collected at the centre. The second is, that a hollow spherical shell of matter exercises no effective attraction on a particle placed anywhere within it. Now, in the case of experiments made with a pendulum at the top and bottom of a coal-mine, the pendulum is acted upon in the former instance by a force equivalent to the attraction which the whole quantity of matter contained in the earth would exert if it were collected at the centre; in the latter instance the quantity of attracting matter is less than in the former by the spherical shell, whose thickness is equal to the distance between the top and bottom of the mine, but the distance of the particle from the centre of attraction is less. It is clear then, that experiments founded on the principles to which we have just alluded, enable us to weigh the whole mass of the earth against an exterior shell of a given thickness; and therefore if the density of the shell (or at any rate the density of the parts which are nearest the mouth of the mine, and on which the attraction exerted by the shell upon the pendulum mainly depends), be ascertained by observation, we shall hence readily deduce the value of the mean density of the earth. Mr. Airy's experiments on the rate of oscillation of the pendulum at the top and bottom of the Harton colliery were made in the summer of 1854. Several English observatories co-operated in their execution by furnishing assistant observers. The Electric Telegraph Company supplied the means of establishing simultaneous galvanic signals between the upper and lower stations. The observations consisted of 104 hours of incessant observations of one pendulum A, above, and another pendulum B, below; then of 104 hours with B above, and A below; then of 60 hours with A above and B below: then of 60 with B above and A below. It appeared from these experiments that the lower pendulum was accelerated 2·25″ per day, or in other words, that the force of gravity was more intense at the lower station than at the upper by $\frac{1}{19190}$th part. The final conclusion which Mr. Airy deduced from these experiments was, that the mean density of the earth is 6·623, the mean density of water being represented by unity. This result, it will be seen, is considerably higher than any value of the same element hitherto found.

The most recent operations for determining the mean density of the earth are due to Colonel James, Superintendent of the Ordnance Survey, who, in 1855, caused a series of celestial observations to be made to the north and south of Arthur's Seat, near Edinburgh, for the purpose of ascertaining the amount of deflection caused by the attraction of the mountain. The resulting value of the mean density was found to be 5·316, with a probable error of 0·054. Colonel James purposes, as soon as the details of the survey of Ben Nevis have been completed, to obtain a new solution of the important problem of the mean density of the earth by determining the amount of deflection caused by the attraction of that mountain, which is the highest in the British Isles, and appears to be in other respects well adapted for the object in view.

The reader may consult the following recent works on this subject: 'Experiments with the Torsion-rod, for determining the mean density of the Earth,' by Francis Baily, Esq. ('Mem. Ast. Soc.,' vol. xiv.); 'Account of Pendulum Experiments undertaken in the Harton Colliery, for the purpose of determining the mean density of the Earth' (with a Supplement), by G. B. Airy, Esq. ('Phil. Trans.' 1856, vol. cxlvi.); 'On the deflection of the plumb-line at Arthur's Seat, and the mean specific gravity of the Earth,' by Capt. Clarke,* R.E. ('Phil. Trans.' 1856, vol. cxlvi.)

EARTHENWARE. The art of moulding earthen vessels for domestic use appears to have been practised in the earliest ages, and among the rudest nations. It is at once the most ancient and the most widely diffused of the arts. In newly-discovered countries it has been found that the use of earthen vessels is familiar among people otherwise little acquainted with the arts of civilised life. Vases have been discovered in the ruins of temples and palatial buildings, constructed by the Aztecs, and other aboriginal tribes of central America; and there is strong evidence for believing that these vessels were the manufacture of the country in which they were found. The potter's wheel is represented in the sculpture and painting of ancient Egypt; frequent reference is made to it in the scriptures of the Old Testament; it must have been in use from a very remote date in ancient Assyria, China, and Japan. In Greece, Rome, and Etruria the potter's art was cultivated with the greatest diligence from the earliest and rudest period of their respective histories, to that of their highest prosperity and refinement. The art indeed arrived at a point of great advancement among the oldest of these nations. In ancient Egypt were made vases and other articles of very elegant forms, as well as common ware for domestic use. From the analyses made at the laboratory of the Museum of Practical Geology, it appears that the pastes or bodies used in making Egyptian earthenware, as seems indeed to have been the case with most ancient pottery, were merely "the natural clays selected for their fitness to the purposes for which they were intended." Glazes or enamels were used by the Egyptians for covering small figures made of a frit of sand, but it is believed that it was not till the later periods of their history that they acquired the art of applying vitreous glazes to their earthenware proper. The Assyrian and Babylonian pottery, as Mr. Birch remarks in his 'History of Ancient Pottery,' "although it bears a general resemblance in shape, form, and use, to that of Egypt, has certain specific differences. As a general rule it may be stated to be firmer in its paste, brighter in its colour, employed in thinner masses, and for purposes not known in Egypt." The Assyrians were, from a very early period, fully acquainted with the use of siliceous and metallic glazes or enamels, and produced them of brilliant colours. Very little of their earthenware has, however, been recovered.

In the hands of the Greeks, vessels of earthenware assumed forms of the most perfect grace and symmetry; and much additional interest was imparted to them for future ages by the practice of painting on them designs which serve now as the truest reflex of Greek painting of the several periods, and afford an almost limitless store of illustration of Greek customs, mythology, &c. The earliest remaining examples of Greek fictile vases are of a pale yellow clay, and have the designs rudely painted of a dark reddish brown. Later, the figures were painted in a black glaze on a pale or red ground. But in the best period of Greek art the earthenware was formed of a reddish substance, which was glazed black; the figures of the design being left of the natural red of the ground. The shapes are of almost infinite variety, but almost invariably marked by the most beautiful simplicity of outline. The pottery of Athens was the most celebrated in Greece, and Athenian vases were offered as prizes in the public games. That of Samos was famous in the days of Homer. With the decline of Greece, all its arts gradually declined, and eventually perished together. Ancient Greek vases are among the most esteemed objects in museums of antiquities: during the last century in particular, extraordinary prices were given for fine specimens: a famous vase, containing a representation of the last night of Troy, was purchased for the Museo Borbonico for 1500*l.* But owing to the vast numbers of them, and of Etruscan vases, which are essentially similar in character, which have been found, the prices have fallen considerably, though very high prices are still readily given for superior examples. [VASES.]

Roman pottery is, in an artistic point of view, of far less value than that of Greece, but as a manufacture much of it is of a very superior quality. The use of earthenware for domestic purposes was almost universal with the Roman people, and wherever they settled they appear to have carried the manufacture with them; not only Roman pottery, but traces of kilns for the firing of the ware having been found in most of the countries in which were Roman settlements. The ware itself is usually of a bright red colour, given to it by the introduction of a peroxide of iron into the paste, and it bears a brilliant glaze. M. Brongniart calls particular attention to the perfection of workmanship exhibited in this ware, in the making of which he says most of the processes now in use appear to have been employed.

With the fall of the Roman empire the arts for a time perished also.

---

[*] Communicated by Colonel James, under whose superintendence the whole operation was conducted.

The ceramic art appears to have lingered longest in the Lower Eastern empire, and from thence to have been acquired by the civilised Arab races who played so important a part in the history of the 9th and following centuries. The Moors of Spain were especially proficients in this art, as is shown, not merely in the beautiful tiles of enamelled earthenware with which they decorated the Alhambra and other of their great buildings, but in vases and other earthenware articles still preserved in public museums. To them, in fact, is due the preservation of the art, and the direction it took upon its revival in Spain and Italy in the early part of the 15th century. The Moorish works continued to flourish till the expulsion of that people from Spain; they were continued, though with little comparative success, by the Spaniards.

The famous Italian Majolica ware, now in such repute with collectors, owes its name to Majorca, the largest of the Balearic Islands, where, whilst it was held by the Moors, was a large manufacture of earthenware, or an emporium for its sale. The island was taken by the Pisans in 1115, and immense spoils were carried by the victors to Pisa; but whether it was from Majorca that the art itself, as well as the name, was derived, is not certain. The earliest so-called majolica ware of the Italians is, however, beyond doubt an imitation of the Moorish ware. But it was not till the 14th century that the Italian pottery began to assume a decorative character, though, according to Pessari ('Istoria delle Pitture in Majolica'), vessels made of red clay at Pesaro, were covered with an opaque coloured, and also a thick white, glaze in the previous century. The so-called mezza-majolica, with patterns of a Moorish character, surrounding portraits, figures of saints, &c., seems to have been first made at Pesaro, where, from about the middle of the 15th century it was produced of so superior a quality as to be regarded as sufficiently valuable to offer as presents to sovereign princes and persons of distinction. The manufacture spread thence into other parts of Italy, and was zealously encouraged by the several princes. Urbino, Gubbio, Castel Durante, and other cities became especially famous for their majolica. At Urbino, artists of great ability were called into requisition to paint the designs upon the vessels; and from the designs of Raffaelle being very frequently copied, and in later years it being reported that Raffaelle himself sometimes painted upon earthenware, the ware itself was long commonly known in this country as Raffaelle ware. It is now, however, generally admitted that there is no ground for supposing that the great painter ever so employed his pencil, the painting being generally executed by artists who devoted themselves to this particular occupation. Most of the majolica ware bears a general resemblance, but that of Gubbio is distinguished by a brilliant lustre, produced by the use of a stanniferous glaze, for the production of which an artist known as Maestro Giorgio, but whose real name was Giorgio Andreoli, who flourished during 1485–1532, was particularly famous. The coloured relievi of Luca della Robbia (1400–81) was formed of earthenware, or glazed terra-cotta, but it hardly belongs to our present subject, though his labours doubtless contributed greatly to the improvement of Italian earthenware generally.

The fine Majolica—or that which owes its celebrity to the beauty of its designs—is considered to have been produced in its greatest perfection from 1540 to 1568. It then began to decline, and the art of making it was finally lost by the early part of the 18th century; majolica having come to be regarded as barbarous, as Oriental porcelain became the dominant fashion. In our own day we have seen the collecting of majolica ware become a passion; and specimens of it, which but a few years ago would hardly have received a second glance, are now regarded as among the most precious ornaments of the museum and the palace. Plates of fine majolica, and of the lustrous ware of Maestro Giorgio, the size of an ordinary dinner plate, have been sold by public auction for as much as 150*l.* each; and large dishes and other articles of less ordinary character, for a much greater sum. A majolica plate, 9½ inches in diameter, now in the South Kensington Museum, will well illustrate the rapid growth of the majolica mania. At the Stowe sale (1848) it was purchased by a London dealer in these "curiosities," for 4*l.* The following year he sold it to Mr. Bernal for 5*l.* At the sale of that gentleman's collection in 1855, it was purchased for the South Kensington Museum for 120*l.* The plate is interesting chiefly as containing a representation of a majolica painter at work. Of late years the manufacture of spurious majolica ware, as well as spurious Greek and Etruscan vases, has been brought to such perfection by those inimitable and most industrious forgers of every object of ancient art, the Italians, that even skilful archæologists and collectors find it extremely difficult to detect the imposture.

In France, earthenware was made as early as the 12th century; and that of Beauvais had become celebrated in the 14th; but the impulse to the manufacture of really decorative ware appears to have been imparted by the establishment of a pottery at Nevers, and the introduction of Italian majolica workers by Catherine de' Medici. The most characteristic old French earthenware, however, is that of Bernard Palissy (1510–89), of which, the most remarkable has raised figures of fishes, reptiles, fruit, and other natural objects, imitated in their actual colours; and which, in pecuniary value, rivals majolica. In Nuremberg and some other parts of Germany, and in Holland, the manufacture of enamelled ornamental earthenware was pursued with great success during the 16th and 17th centuries. Holland earthenware, under the name of delft, was, prior to the growth of the Staffordshire factories, that ordinarily used in this country. The earthenware drinking jugs of quaint shapes, but some far from inelegant, are familiar from their constant occurrence in Dutch pictures.

The Britons must have understood the potter's art before the Roman occupation, since urns of earthenware have been found in barrows in different parts of the kingdom. Vestiges of considerable Roman potteries have been discovered in many parts of this island, particularly in Staffordshire; at Castor, Northamptonshire; at Lincoln; in the New Forest; and on the site of a former island in the Queen's Channel near Margate. Probably rude pottery continued to be made in England. Decorative tiles for ecclesiastical purposes were wrought during the Norman dynasty; and perhaps, in one form or other, the making of earthenware never ceased to be practised here. In the 16th and 17th centuries, it is evident, from the many specimens of drinking vessels, dishes, &c., in private collections, that a good deal of attention was given to the making of ornamental earthenware, the principal seats of the manufacture being Lambeth, Burslem, and Liverpool. But, as already said, till far into the 18th century, England was chiefly indebted for its ordinary domestic earthenware to Holland, and for superior kinds to Germany and France. English earthenware and porcelain are now, however, not only brought into general use in this country, nearly to the exclusion of foreign goods, but earthenware is also largely exported to almost every part of the known world, and even to those countries where the art was previously prosecuted. M. Faujas de Saint Fond observes on this subject: "Its excellent workmanship, its solidity, the advantage which it possesses of sustaining the action of fire, its fine glaze impenetrable to acids, the beauty and convenience of its form, and the cheapness of its price, have given rise to a commerce so active and so universal, that in travelling from Paris to Petersburg, from Amsterdam to the furthest part of Sweden, and from Dunkirk to the extremity of the south of France, one is served at every inn upon English ware. Spain, Portugal, and Italy are supplied with it; and vessels are loaded with it for the East Indies, the West Indies, and the continent of America." Since this intelligent French traveller wrote, the distribution of English earthenware all over the world has vastly increased. England is mainly indebted to Josiah Wedgwood for the extraordinary improvement and rapid extension of this branch of industry. Wedgwood's success was not the result of any fortunate discovery accidentally made, but was due to patient investigation and unremitting efforts. He called upon a higher class of men than had usually been employed in this manufacture to assist in his labours; and in prosecuting his experiments he was guided by sound scientific principles. The early and signal success which crowned his first exertions only served as an additional motive for continuing his pursuit. One of the principal inventions of Wedgwood was his *table ware*, known afterwards as *queen's ware*, in consequence of the patronage of Queen Charlotte, who commanded it to be thus designated. It is a dense and durable substance, covered with a brilliant glaze, and capable of bearing uninjured sudden alternations of heat and cold. From its first introduction, it was manufactured at so cheap a rate as to render it an article within the reach of all. Soon afterwards, embellishments were introduced, which added only a little to the cost of the article; first, a coloured edge or painted border was added to the queen's ware; and, lastly, printed patterns covering the whole surface. Wedgwood's more beautiful inventions were—a *terra cotta*, which could be made to resemble porphyry, granite, Egyptian pebble, and other beautiful stones of the siliceous or crystalline kind: a black porcelainous biscuit [BISCUIT] very much resembling basalt in its properties, and therefore called *basalt;* a white and a cane-coloured biscuit, both smooth, and of a wax-like appearance; and another white biscuit, distinguished as *jasper*, having in general all the properties of the basalts, with a very important addition, namely, the capability of receiving through its whole substance, from the admixture of metallic oxides, the same colours as those oxides communicate to glass or enamel in fusion. This peculiar property of the jasper-ware renders it applicable to the production of cameos and all objects required to be shown in bas-relief; as the ground can be made of any colour, while the raised figures are of the purest white. Mr. Wedgwood likewise invented a *porcelain biscuit*, nearly as hard as agate, which will resist the action of all corrosive substances, and is consequently peculiarly well adapted for mortars in the chemist's laboratory.

We have only been able to treat very cursorily the history of earthenware; those who may desire further information respecting it will find ample particulars in Alexandre Brongniart's 'Traité des Arts Céramiques, ou des Potteries considerées dans leur Histoire, leur Pratique, et leur Théorie,' Paris, 1844; 'A History of Ancient Pottery and Porcelain: Egyptian, Asiatic, Greek, Roman, Etruscan, and Celtic,' by Samuel Birch, London, 1857; and 'A History of Pottery and Porcelain, Mediæval and Modern,' by Joseph Marryat, London, 1857, which, together, cover the entire field of inquiry, and supply, with their references, materials for extending research as far as may be desired. It may not be out of place, however, to add that the public museums of the metropolis now afford the student means of obtaining that actual knowledge of the products of the art which books alone cannot possibly supply. The British Museum contains many specimens of the pottery of ancient Egypt, Assyria, and Babylonia. Its collections of Greek and Etruscan vases occupy two spacious rooms. Of Roman pottery, including that found in Great Britain, it contains numerous examples. It has also many specimens of Celtic and ancient British pottery; and it has a varied and rich collection of the Hispano-Moorish, Majolica, and Delft earthenware spoken of above. But in these latter classes the South Kensington Museum is still richer. The specimens of majolica in the British Museum number somewhat under 200, in the South Kensington Museum they are about 500. In this latter museum the majolica is arranged according to the towns in which it was produced. Both museums, however, contain many very fine and characteristic examples; and South Kensington is rich in early French and English ware. Finally, at the Museum of Practical Geology in Jermyn Street, are characteristic, though not numerous, examples of the potter's art of almost every period from the most ancient down to the present time; together with specimens of the different kinds of earth, the glazes and the enamels employed in their production. An hour or two spent in examining these collections will give clearer notions on the history of the ceramic art and the character of its productions than can possibly be obtained from mere descriptions.

Although earthenware may be considered as a general term applicable to all utensils composed of earthen materials, it is now usual to distinguish such utensils more particularly into three different kinds; namely, pottery, earthenware, and porcelain. Under the first of these terms are classed the brown stone-ware made into jugs, &c., the red pans and pots in common use, porous vessels, &c. [POTTERY.] Porcelain is distinguished from earthenware as being a semi-vitrified compound, in which one portion remains infusible at the greatest heat to which it can be exposed; while the other portion vitrifies at a certain heat, and thus intimately combines with and envelopes the infusible part, producing a smooth, compact, shining, and semi-transparent substance, well known as the characteristic of true porcelain. [PORCELAIN.] The third-class, intermediate between these two, is the subject of the present article.

The principal ingredients employed in the composition of all kinds of earthenware and porcelain are clay and flint. The nature of the clay used in the manufacture is of great importance, and so also is the combining of it with a due proportion of flint. The clay principally used in the Staffordshire potteries is obtained from Dorsetshire and Devonshire, and is distinguished into the qualities of *brown*, *blue*, *black*, and *cracking* clays. All these clays are of good working quality, and burn extremely white, being free from any impregnation of iron; the blue clay is considered the best. About 70,000 tons of Dorsetshire clay is exported yearly from Poole, for the use of the Staffordshire manufacturers. Another description of clay, superior to any of these, and found in Cornwall, is commonly denominated *China* clay, because similar in its properties to the porcelain earth of China. This Cornwall clay is so indispensable in porcelain, and so valuable in the finer kinds of earthenware, that it may be well to describe here the processes of its preparation, from a paper recently drawn up by Mr. Stokes, of St. Austell.

The disintegrated granites of Cornwall, which are commercially know as *China stone* and *China clay*, were first used as ingredients in potter's clay about 1768, through the instrumentality of Mr. Cookworthy of Plymouth; and the consumption became greatly increased when it was found that, if fused, the disintegrated granite would form a suitable glaze for articles made of the clay. This was the China clay, or kaolin. The China stone was not brought into use till 1802, when a Cornish bed began to be worked, comprising felspar, silica, and mica, without any iron or manganese; if granite contains talc, hornblende, or diallage, it is unfitted to form China stone. The good China stone is found principally in proximity with fissured granitic rocks, near St. Austell. It is believed that the granite has been brought to the states of China stone and China clay by a variety of causes—the alternation of hot and cold weather; the solvent power of rain water; and the action of chemical agents in the air and water. The chief hill or district of the China stone is divided off into several portions, leased by different individuals or companies. The stone is sufficiently hard to need quarrying by gunpowder and the pick; it is raised from the pits, and transferred to waggons near the pits' mouths. It undergoes no preparation, but is at once shipped to Staffordshire, where the potters are left to deal with it as they please. The price is greatly increased by the cost of land carriage to the nearest port of shipment; but now (1859) that the Cornwall Railway is opened, there is a prospect of increased facility of transport. It is supposed that there are about a million tons of China stone in the St. Austell beds. The China stone in its present state consists of a mixture of quartz, felspar, and mica, blended so as to form a homogeneous mass, much resembling granite, but with a texture less compact. Chemically it is a nearly-pure double silicate of potash and alumina, which, when fused, forms a pearl-white translucent mass, firm and resonant; it has an opaque body of nearly perfect kaolin, surrounded by and diffused through a glaze of silicic acid, to which its translucency is due. The China clay or kaolin is more abundant than the China stone, and is shipped to Staffordshire to the extent of about 100,000 tons per annum. It is not, like China stone, confined to one or two localities, but is distributed in many parts of the county. It is found intermixed with quartz and mica in most of the valleys contiguous to hills of disintegrating granite. The substance presents itself as an amorphous whitish-blue powder, often lying contiguous to formations of granite, killas, clay-slate, and grauwacke. The clay assimilates in quality to the granite from which it has been derived; if the felspar be very white, the clay is white; if there is much mica, the clay becomes strong and tenacious. The clay is worked and filtered in large recesses formed in the surface of the ground; allowed to remain till solid; cut into square blocks; conveyed to a drying-yard; and there allowed to remain until white and quite dry. There being some difficulty in drying the clay in wet localities, Mr. Stokes has invented a method of expediting the process; it consists in the use of a number of perforated cylinders, having on them shelves similarly perforated, or made of wire-gauze; these cylinders are kept rotating two hundred times a minute, by four attached multiplying wheels, worked by wind, water, or steam; they have several perpendicular screw-like arms, on each of which are a number of transverse shelves for the carriage of the clay; the rapid action of the wheel causes currents of air to be thrown upon the clay, which soon becomes dry. The blocks are kept in a place where cool dry air can reach them, until shipped to the Potteries. The China clay varies in price from 20*s.* to 50*s.* per ton, according to its purity, hardness, whiteness, and freedom from shrinkage when calcined. Not less than 7000 men, women, and children, are employed in Cornwall in collecting and preparing the China stone and clay.

We will now suppose the requisite ingredients to have reached the pottery establishments in Staffordshire, and will trace the processes of manufacture. In the preparation of the earthenware clay some labour is required before it is in a fit state to be combined with the flint. It is first mixed with very pure water to the consistence of cream: this work is called *blunging*, and in large establishments is performed by means of machinery. The result is a smooth pulp, which is then passed through a series of sieves of increasing degrees of fineness, till at length it is perfectly fitted to enter into the composition of the ware. If the clay were moulded and dried without the addition of any other body, it would certainly crack; as the evaporation of the water with which it is mixed, in order to render it sufficiently plastic for the potter's wheel, would cause it to shrink in the proportion of one part in twelve in drying. In combination with siliceous earth in proper proportions, it bears the action of fire without cracking, while the silica materially improves the whiteness of the ware.

The flints are prepared by being burnt in a kiln, and removed while red hot from the kiln and thrown into cold water. By this operation their attraction of aggregation is lessened, and the labour of grinding them is much facilitated. They are then broken and ground to a very fine powder in a mill constructed for the purpose, the original of which was invented by Brindley. A quantity of water is thrown into the mill with the flints, by which the process is quickened and the health of the workman is preserved, the finer particles of flint being thus prevented from flying off and mixing with the atmosphere which the workmen inhale. The flints, when reduced to powder, are transferred from the mill into another vessel, where more water is added, and the whole is violently agitated by mechanical means; the finer parts are in consequence held in suspension above, and in this state are passed into a reservoir, while the grosser particles are left behind at the bottom of the vat. After subsidence, the supernatant water is drawn off from the reservoir, and the pulverised flint is in a fit state for use. It is considered of a proper fluidity for mixing with the clay when a pint weighs 32 ounces, while an equal measure of the diluted clay should weigh 24 ounces. The proportions in which the clay and flint are mixed vary with the quality of the clay, with the nature of the ware to be produced, and also with the practice of each manufacturer; the flint may form a fourth, a fifth, or a sixth part by weight of the prepared paste. The dilutions of clay and flint being brought together in suitable proportions, are intimately mixed by agitation, and passed, while in a state of semi-fluidity, through different sieves, whereby the whole becomes a smooth homogeneous mass. This mixture, technically called *slip*, is then very carefully evaporated, the mass being frequently stirred and turned over lest a part should become improperly hardened while the remainder continues too fluid. When the clay or paste is removed from the *slip-kiln*, it is well incorporated by beating it with wooden mallets, in order to expel the air which it contains. The next operation is that of cutting it into small pieces, which are thrown together again with all the strength of the workman; and this process is continued until the mass is considered to be in a complete state of consistence. When in this state, the mass is allowed to remain for a considerable period before being used, since it becomes more intimately united by time than by any mechanical means.

The paste, when taken for use, undergoes the process of *slapping*, which is similar in its effect to the last operation, and should incorporate the whole mass so completely, that wherever it is cut it should exhibit a perfectly smooth and uniformly close appearance. The clay, being thus prepared, is now ready for use.

The processes in the forming of earthenware are mainly of three different kinds—throwing, pressing, and casting, which are respectively employed according to the form of the article required.

The operation of *throwing* is performed upon a machine called a potter's lathe, and is used in shaping vessels which have a circular form. By this means the thrower moulds the clay into the form which he desires; chiefly by the fingers and palms of the hands, but in part also by wooden tools. When finished to his satisfaction, he removes his work to a board or shelf, where it is left to dry partially; and when in a particular state of hardness, called the *green state*, well known to the operator, the vessel is in proper order for being further smoothed and shaped in the *turning-lathe*, and for being furnished with handles, spouts, or any other addition. The turning-lathe is similar to that used by the turner in wood, and by means of it, rings, rims, &c., are formed on the vessels. For making dishes, plates, and other similar shallow vessels, a plaster mould is used, which is placed on the block at the top of the upright spindle of the lathe; and the workman continues the process in nearly a similar manner as in throwing. When sufficiently dry to be taken from the mould, the edges are pared with a sharp knife, and the vessels are placed in piles and left to harden, preparatory to their being baked.

A machine called an *engine-lathe*, which has a horizontal movement backwards and forwards, in addition to the rotary motion, is used in giving to earthenware a milled edge. Handles, spouts, &c., are fixed on the vessels as soon as they are taken out of the turning-lathe. They are affixed by means of slip, with which the parts designed to come in contact are moistened; in a short time, when dry, the union of the parts is found to be perfect. Handles, &c., are made by pressure in a small metallic cylinder, which has an aperture in the centre of its bottom, to which plugs of various shaped orifices are fitted; there is likewise a piston, so fixed as to be worked by a screw up and down the cylinder. The cylinder being filled with clay, the piston is inserted, and forces the clay through the orifice at the bottom, and consequently gives it the same form as the aperture through which it was pressed. Being then cut into lengths and bent to the desired shape, the clay is ready, when sufficiently dry, to be joined to the vessel. For ornamental spouts, small ornaments, and other appendages of the like nature, the clay is pressed in moulds, the particular mode of doing which may be readily conceived.

When the vessels are sufficiently dry they have to be submitted to the action of fire. For this purpose they are placed in deep boxes called *seggars*, made of a mixture of fire-clay and old ground seggars, and capable of sustaining the most intense degree of heat without being fused. The seggars are of various sizes, shapes, and depths, adapted to the different pieces which they are to contain. In no case is one piece placed in or on another in the seggar, and all is so arranged that the heat may be equally applied to every part of each. The seggars, with their contents, are then disposed in the oven in such a way that the heat may be distributed fairly throughout: they are built one layer on the top of another until they reach nearly to the top of the oven, each seggar forming a cover to the one beneath it, and the upper seggar in each pile being always empty. The oven is of a cylindrical form, and very similar to the common kilns used for burning tiles. The process of baking usually lasts from forty-eight to fifty hours, during which time the heat is gradually increased, as it would be injurious to the ware to apply a very high degree at first. To ascertain when the baking has been carried far enough, the workman uses tests of common Staffordshire fire-clay, the pyrometer of Wedgwood having been long laid aside. When the appearance is considered satisfactory, the firing is discontinued, and the oven is suffered gradually to cool during twenty-four or thirty hours before the contents are taken out. The ware in this state is called *biscuit*. The glaze is now applied; the pieces are again placed in seggars, and conveyed to the glazing-oven, where heat is applied to them of sufficient intenseness to fuse the glaze; but the heat must by no means be so great as that to which the *biscuit* has previously been exposed, as the glaze would crack or peel off if the vessels were liable to any further shrinking.

The glaze generally used for common kinds of earthenware is a compound of litharge and ground flints, in the proportion of ten pounds of the first to four pounds of the latter. This method of glazing is however highly objectionable on account of its injurious effects on the health of the workman; while the lead being soluble by acids, makes a most pernicious glaze for vessels which are used for containing articles of prepared food. Glazes for porcelain and the finer kinds of earthenware are generally made with white lead, ground flints, ground flint-glass, and common salt. But almost every manufacturer uses a peculiar glaze of his own, the manner of making which he keeps in as much mystery as possible. Some glazes are made without the admixture of any lead, and in the whole of the better glazes this ingredient enters in so small a quantity as not to be injurious. The manner of applying the glaze is, to reduce the ingredients to powder, mix them with water to the consistence of cream, and then merely dip the pieces into the preparation, and withdraw them immediately, taking care that all the parts have been wetted with the glaze.

The kind called *dipped-ware* receives its coloured ornament in a singular way. After the basin or other vessel has been turned, it is fixed to a wheel, and made to rotate while the colouring is being effected. If, as is often the case, the colours are brown, yellow, and blue, the workman prepares three kinds of coloured liquid or creamy clay. A portion of these three he puts into a kind of funnel having three compartments, in such a manner that all three remain separate, and yet flow out of three adjoining apertures simultaneously. This funnel the workman holds over the vessel while revolving, in such a way that a little stream of tri-coloured paint shall drop upon it and form bands, stripes, spots, or curves; the three colours being contiguous, and yet distinct on the vessel.

When the earthenware is to be *printed*, it undergoes this process previously to glazing. It is thus performed: the landscape or pattern is engraved upon copper; the desired colour, being mixed with linseed-oil, is laid on the plate; and impressions are taken off on tissue-paper, in the manner usually employed by copper-plate printers. The paper, wet with the colour, has then all the blank parts cut away, leaving only the pattern entire, which is applied lightly to the ware when in the state of biscuit. It is then rubbed with a piece of woollen cloth, rolled tightly in the form of a cylinder, till the colour is pressed sufficiently into the ware. In this state the whole is left for an hour, when it is placed in a cistern of water, so that the paper becomes sufficiently moistened to peel off readily, having transferred to the biscuit the colour and impression which it had received from the copper-plate. When the pieces thus printed are sufficiently dry they are placed in an oven and exposed to a gentle heat, in order to dissipate the oil: they are then in a fit state to receive the glaze. Till within the last few years, blue produced from the oxide of cobalt was the only colour employed, but at present many other colours are printed with equal facility.

The art of painting, as applied to these interesting manufactures, relates to porcelain rather than to earthenware, and will be noticed in a later article [PORCELAIN]. The so-called *lustre-ware* is an earthenware to the surface of which a peculiar metallic effect is given. The metallic oxides used for this purpose are intimately mixed with some essential oil, and then brushed entirely over the surface of the vessel; the heat of the enamelling oven dissipates the oxygen, and restores the oxides to their metallic state, but with their brilliancy somewhat diminished. The imitation of gold and silver is very successful in some of these specimens.

One of the most important features connected with the English earthenware manufacture is the process just described, of imparting a pattern by means of printing, generally with a blue ink or pigment, but sometimes with black or other colours. Discussions have recently taken place, in reference to the *designing*, the *printing*, and the *applying* of these patterns, which it will be well briefly to notice here.

Concerning the designs for earthenware adornment, persons of taste have long speculated why the well-known willow pattern maintains its place so persistently in the market. Designs in every way more artistic are occasionally tried; but the dealers find this old pattern still sells the best, and therefore the potters adopt it more largely than any other. In 1856, Mr. Wallis, in a paper on 'Design as applied to Ceramic Manufactures,' read before the Society of Arts, adverted to the great influence exerted on the progress of the porcelain manufacture by the eminent firms of Minton and Copeland, and then made the following observations on the earthenware manufacture:—"Others have followed who, applying a better style of art to less exceptional articles than those produced by those two firms, have certainly aided in no slight degree the recent improvements. It is quite evident that at the present time, whatever fault may still be found with the subjects employed for decorating the cheaper wares, yet that the character of the art employed is much higher than formerly. In the blue-transfer ware, for instance, there is a decided tendency to mosaic forms, less attempt at projection in light and shadow; and although the details are more architectural than fictile, yet the result is felt to be more suited, alike to the use of the article, the surface decorated, and the method of ornamentation. In their forms, too, we can trace the influence of the merest elementary outlines in use in our schools of art, of which that established in the Potteries about eight years ago has been one of the most practically useful." There can indeed be no question that the designs are improving; and it is curious to observe the mode in which a reason has been sought for the persistence of that one particular pattern which no person pretends is artistic in any sense. In a discussion which followed the reading of Mr. Wallis's paper, Mr. Lockett, a well-known engraver for manufacturing purposes in Manchester, said:—"The world-wide celebrity of the willow-pattern in crockery is an instance of demand, where usefulness and economy are the chief considerations. The ware is well covered by the pattern; and in case of breakage there is no difficulty whatever in replacing them. The willow-pattern is to be found almost everywhere; whereas more elegant designs are often difficult, if not altogether impracticable, to replace; or they might require to be made expressly, if the manufacturer can be found, at extra cost and considerable inconvenience. I feel persuaded that the willow-pattern is seldom if ever bought for the beauty of the design; it is preferred only for its usefulness and convenience. Therefore the extensive demand for it ought not to be taken as a proof of deficient taste in the public."

In relation to the *engraving* of the designs, whatever they may be, several suggestions have been brought forward within the last few years. Mr. Lander, an engraver of Bristol, has recently (1859) patented the following: He proposes to engrave the subject on a copper-plate; take as many electrotype copies from this as there are to be colours (supposing it to be a specimen of polychrome earthenware, which seems to be in Mr. Lander's view); erase portions from each cast, so that what is *left* on any one shall be *removed* from all the others; and then finish up each plate with the graver. A print is to be taken on paper, in the ordinary manner of colour-printing; that is, the plates are to be affixed to a frame, with guides to preserve the register; each plate is to be used only for one colour, and each is to be impressed on the paper in turn. It is obvious that this method will only be available for costly kinds of earthenware. Another suggestion is that made by Mr. Joubert, founded on the method of hardening copper-plates by *steeling* or *acierating*. Engraved copper-plates can, as is well-known, be multiplied almost without end by the electrotype process; thereby enabling one design to be available for an enormous number of printed impressions. These copper casts, however, are very soft, and yield only a few hundred impressions before they exhibit signs of wear, which are an eyesore to the engraver of high-class works. Hence, in 1857, M. Garnier, of Paris, tried the efficacy of copper-plates *coated with iron or steel after the engraving*, yet so exquisitely as not to injure the fineness of the lines. His experiments resulted in a patent taken out in 1858 by M. Jacquin. According to this patent, the engraved copper-plate is immersed in a trough containing a solution of a salt of iron, and containing also a sheet of iron. When the copper and the iron are placed in connection with the opposite poles of a galvanic battery, a complex electro-chemical action ensues, and a film of pure iron is deposited all over the engraved copper-plate, so wonderfully thin and uniform as to leave the handiwork of the engraver uninjured. A copper-plate so prepared has, it is asserted, been made to yield nearly as many impressions as another plate engraved on steel. When the beauty of the impressions begins to fade, the acierating may be repeated; and so a third, and still greater number of times. The controversy to which this invention has given rise among the engravers and printers of high-class works of art, we need not touch upon here; but it may be well to quote some observations made by Mr. Joubert in 1859, concerning the application of this principle to the printing of earthenware: "Some years ago, it was deemed desirable in potteries to supersede the necessity of having a large number of copper-plates engraved with the same design. Steel-plates were suggested; but the engravers found that they had to cut the lines so deep, in order to hold the large amount of colouring matter necessary, that there was great difficulty in using this hard metal. A further objection to the use of steel for this purpose, was that the smoothness of the surface prevented it from holding the oily description of colouring matter used. In the ordinary mode of printing, the cleaning of the surface of the plate is effected by the palm of the hand; but for earthenware, the plate is scraped with a spatula, and by that means the oily ink is apt to be dragged out of the lines." As a remedy for this evil, some of the potters have begun to use acierated copper-plates. Some persons have suggested that it would be better to acierate the *surface* of the plate only, leaving the engraved lines untouched—on the ground that copper receives the oily ink better than steel; but to this it has been replied, that a superior plan would be, to devise a new kind of colouring vehicle—which is quite within the range of inventive art. One more novel suggestion is all that we can make room for: Mr. R. Smith of Blackford has suggested that earthenware might receive a great variety of colours without the employment of engraved plates at all, by employing galvanic agency. Supposing a piece of earthenware to be about to receive a device in purple, he would place it for a few seconds in water; dip it into a solution of muriate of tin; connect the interior of the vessel with the negative pole of a galvanic battery by means of a strip of lead; connect a chain to the positive pole with a bit of gold wire at the end; and trace any device on the vessel by means of the gold wire, keeping the lead strip as near to it as possible on the inner surface. Mr. Smith conceives that a purple device would be produced by the chemical change of the ingredients into the purple precipitate of cassius. The colour would be baked in and glazed in the usual way. Or he would cut a pattern in gold foil; mount it on a band of gutta-percha; place the band round the vessel to press the gold close to the earthenware; and set the battery to work, to produce a pattern following the outline of that of the gold foil. To vary the effects, by producing blue or other colours instead of purple, platinum, palladium, silver, copper, iron, or cobalt, may be used instead of gold; and nitro-muriatic acid or ferro-cyanide of potassium instead of muriate of tin. The inventor appears to think that the precious metal deposited, from its extreme thinness, would not be so costly as the engraving, paper, printing, &c., in the ordinary method; but this, as well as many other points connected with the suggestion, remain to be proved.

We spoke above of one of the recent novelties as being concerned, not with the *designing* or *engraving*, but with the *applying* of the device. This is the remarkable method recently patented by Mr. Collins. He can enlarge or diminish an engraving without re-engraving the plate. The processes are not yet placed before the public in such a form that they can be described minutely; but their rationale is somewhat as follows: Let us suppose, first, that the device is to be enlarged. It is engraved on copper; an impression is taken from it, with a peculiar ink and in a peculiar way, on the flat surface of a substance in which india-rubber is the chief ingredient; this surface is stretched by a most careful process, acting on every part of it equally, so as to produce no distortion of the device, although it may be twice as long and broad, or cover four times the area, as before. From this stretched surface an electrotype cast is obtained; and from this cast impressions may be printed on paper. Let us suppose, on the other hand, that the device is to be diminished. It is engraved on copper; an impression is taken from this on an india-rubber surface *already in a state of tension*—that is, the surface is stretched before instead of after the taking of the impression. The tension is then removed, by which the surface is brought back to its original size; and the device appears upon it in a much smaller form than on the original copper-plate: perhaps only one half as long and broad, or covering only one-fourth the area. An electrotype cast is taken, and the printing proceeds. An engraving may thus be copied on an enlarged or a diminished scale, without re-engraving. The possible applications of this very remarkable invention to the fine arts, we will not touch upon in this article; but it may be well to mention that a joint-stock company, now forming for carrying out the patent, counts much upon its valuable employment in printing earthenware. Staffordshire now produces sets, or suites, or services of useful earthenware, in which the same pattern is depicted on all the cups, saucers, plates, dishes, basins, and other pieces—some small and some large; some circular and others oval. Hitherto it has been necessary to engrave as many plates as there are sizes and shapes in the suite; but now it is hoped that one plate will suffice for all or nearly all. It can be expanded or contracted to suit circular articles of different diameters; or, if stretched or contracted more in one direction than the other, it can transform a circular device into an oval. Specimens have already been produced, showing the application of this principle in a very striking way.

The earthenware factories of England are mostly situated in that remarkable district of Staffordshire known as the Potteries. The towns, considered topographically, are noticed in the GEOGRAPHICAL DIVISION of this CYCLOPÆDIA; therefore we may, in this place, simply say of them that Tunstall, Burslem, Cobridge, Hanley, Shelton, Etruria, Stoke, Fenton, Longton, and Lane End, and many other places whose names are less known, form virtually one town ten miles long, almost the whole of the inhabitants of which are supported by the earthenware and porcelain manufactures. Good clay is found there for the seggars or baking vessels, and for bricks for kilns, &c.; cheap coal is dug in the vicinity; and there is easy transport, by canal and railway, to the great shipping port at Liverpool. The pottery works (often called *banks* by the work-people) have a general similarity one to another. Each presents to view on the exterior its large, lofty, dark-coloured structures, which are the hovels or casings surrounding the ovens in which the ware is baked; and each has in its immediate neighbourhood whole streets of houses, in which the work-people reside. Inside, the buildings generally surround a large number of open courts or passages. There is little symmetry or elegance, for many of the establishments have gradually grown by the addition of new buildings to those originally used. So vast are the quantities made, that each cluster of buildings is usually devoted to a particular branch of the manufacture—dishes in one building, plates in another, saucers in a third, coloured ware in a fourth, printed ware in a fifth, and so on.

The extent of the earthenware and porcelain manufacture in England is not correctly known; a few years ago it was roughly estimated at 2,500,000*l*. annually. Of the exports we have better means of judging. The declared values in three years, separated by intervals of seven years apart for the purpose of comparison, were set down thus:—

	£
1844	766,000
1851	1,121,000
1858	1,151,000

This last named value is supposed to have been represented by about 100 million pieces; if so, it presents an average of less than threepence each piece or vessel, showing that the bulk of the export is in the form of common cheap earthenware; indeed the familiar earthenware plates, cups, and saucers, are the chief articles. From the following entries it will be seen that the United States are our best customers for these commodities:—

			£
Exported in 1858	to the	United States	379,000
"	"	Brazil	92,000
"	"	British America	54,000
"	"	East Indies	82,000
"	"	Australia	106,000
"	"	Other countries	438,000

The time seems to be approaching when the United States will make earthenware for themselves, instead of buying so largely from us. At Pittsburg in Pennsylvania, and at Liverpool on the Ohio, large pottery establishments have arisen within the last few years. Missouri supplies fine clay for earthenware, and Delaware still finer for porcelain; and as fuel is cheap, the manufacturers are now largely producing for the western states of the Union. A kind of queen's ware is made, with raised devices on a cobalt blue glaze. There is also a flint-enamelled ware, made from a very white clay found near Charleston. One peculiar manufacture is that of earthenware knobs for common locks; they are made of a striated mixture of red and yellow clay, coated with a strong brown glaze; and a hole for the spindle is made by the process of casting the knob. The article produced is cheap, durable, and convenient.

The continent of Europe produces no earthenware, in quality and price combined, equal to that of England. The ceramic manufactures are there eminent rather for the porcelain than the earthenware. [PORCELAIN.]

EARTHQUAKES are the most terrific of all natural phenomena The solid surface of the globe is put in motion by them, and assumes an appearance which in some cases may be compared with the sea when agitated by the wind.

The least dangerous of these phenomena are those which by the Creoles of South America are called *Tremblores*, a term which may be translated by *tremors*. The surface of the earth is put in a trembling motion, by which such objects as are not well supported are thrown to the ground, and even walls are split, but the damage does not extend farther. Life is safe, and property but slightly injured. These tremors are by far the most common kind of earthquakes, and occur in some countries of South America, especially in Chile, almost every day, at least in certain seasons.

The *terremotos* of the Creoles, or proper earthquakes, give to the surface either horizontal oscillations, not dissimilar to the waves of an agitated sea, or they consist in violent perpendicular upliftings, so that it would seem as if repeated explosions were exerting their force against the roof of a subterraneous cavern, threatening to burst it open and to blow into the air everything placed over it. By these earthquakes walls are overthrown, and fissures are produced in the ground. The latter are frequently more than a foot in width, and sometimes water gushes out of them like a fountain.

Nothing makes such an awful impression on the senses as an earthquake. The earth is violently convulsed, heaving up and down in a manner hardly conceivable by those who have not witnessed it. The tottering buildings, the falling of the tiles, and the crashing of the timbers of the roofs, completely distract the senses. Fear drives men from their houses; but they do not always find safety out of doors. No person can stand without support: people cling to one another, to trees, or to posts. Some throw themselves on the ground; but the motion of the earth is so violent that they are obliged to stretch out their arms on each side to prevent themselves from being tossed over. Animals are equally alarmed. They stand with their legs spread out and their heads down, trembling violently. The air itself seems to participate in the convulsion, for the birds fly about wildly. Meanwhile the sea retires from the shore; but after a few minutes it returns in a high wave, which advances like a watery wall with incredible velocity, and covers all those tracts which are not more than fifty feet above high-water mark. It rushes back with equal velocity. This motion of the sea is repeated as long as the shocks of the earthquake are violent. Vessels sailing along a coast convulsed by an earthquake feel also a motion quite different from that produced by gales or currents. The loss of life by earthquakes is sometimes considerable. It is chiefly produced by the falling of the buildings when the shock is so unexpected that the inhabitants have not time to escape. In some cases the overflowing of the sea has been fatal to a great number of persons. People have also been swallowed up by the fissures caused by earthquakes.

Earthquakes are generally preceded and sometimes attended by a subterraneous noise, which is compared by some to that of a very heavy artillery waggon rolling quickly over a stone pavement at a distance; by others, to the echo of distant thunder in a mountainous country. It is worthy of remark that this noise is sometimes heard without any earthquake taking place, as in 1784, at Guanaxuato, in Mexico, and that it has been as audible in places situated at a considerable distance from the seat of the earthquake as in those which experienced the shocks. There are also many cases on record in which the earthquakes have not been attended by such subterraneous noise.

The single shocks of an earthquake last from a few seconds to two or three minutes. Sometimes they follow one another at short intervals. It is remarkable that generally either the first or one of the first shocks is the most violent, and that they afterwards gradually decrease in force. Sometimes they return for several days, and even weeks; and in some places, as at Copiapò, in Chile, they are of daily occurrence.

Earthquakes are sometimes experienced over an immense tract of country. The great earthquake in Chile (in 1835) was felt at all places between the Island of Chiloe (40° S. lat.) and Copiapò (27° S. lat.): consequently over 13° of latitude. It extended from the island of Juan Fernandez to the town of Mendoza, on the east side of the range of the Andes, over 10° of longitude. But when earthquakes extend over such an immense tract of country, some districts are always convulsed with greater violence, and these may be considered as the centre of the earthquake. The farther a place is removed from these centres, the less violent, as a general rule, are the shocks.

We know little, or rather nothing, of the origin or cause of earthquakes. It may, however, be considered as certain that they are due to the same agency which produces volcanic eruptions. These eruptions are frequently preceded by earthquakes; and whenever, in places situated near active volcanoes, it is observed that no smoke issues from their craters, the inhabitants begin to fear the approach of an earthquake.

It is not quite certain whether or not there is any connection between the state of the atmosphere and the phenomena of earthquakes. It is not improbable that such is the case with the slighter shocks, the *tremblores*. They commonly occur, or at least are by far most frequent, at the time of the changes of the seasons, in Guatemala as well as in Chile. But the more violent concussions seem to be quite independent of the seasons, and they occur both in calm and cloudless weather and in storms and during rain. In some instances they have been preceded by luminous meteors.

Ancient authors, especially Thucydides, frequently mention earthquakes; but only in general terms. Yet we learn enough from these slight notices to show that they were often equal in violence to those which in modern times have convulsed the continent of Europe and Asia. (Thucyd. i. 101; iii. 89; v. 50; viii. 41.) No detailed description of an earthquake in Europe or in the old continent exists before that which, on the 1st of November, 1755, almost destroyed the city of Lisbon. This is probably the most destructive earthquake which has ever occurred in Europe. The number of persons that perished by it is stated to have been 30,000. In February and March, 1783, the north-eastern part of Sicily and the southern portion of Calabria were convulsed by repeated and violent shocks, which overthrew the town of Messina, and killed many thousands of its inhabitants, as well as many persons in Calabria. One of the last considerable earthquakes in Europe extended over the middle of the kingdom of Naples, and was most destructive in the districts lying along the declivities of Mount Matese (41° 30′ N. lat.). The number of persons who perished by it amounted to 3274, besides 1615 who were wounded. In 1857, on December 16, two shocks of earthquake were felt in Southern Italy, especially in the province of Basilicata, by the destruction of buildings occasioned by which, at least 22,000 human beings were destroyed and 4000 wounded. It has been computed by Dr. Lacaita, that in the course of seventy-five years, from 1783 to 1857, the kingdom of Naples lost at least 111,000 inhabitants by the effects of earthquakes, or more than 1500 per year, out of an average population of 6,000,000.

On the first day of the year 1837, the countries along the eastern extremity of the Mediterranean, especially Syria, were violently agitated by an earthquake. The towns of Damascus, Acre, Tyre, and Sidon, suffered great damage, and Tiberias and Safet were entirely destroyed. It is stated that about 6000 lives were lost.

America is more subject to earthquakes than any portion of the Old World (except perhaps the Indian Archipelago and its vicinity), but they are only strongly felt between 20° N. lat. and 40° S. lat.; and it is not the whole country included between these latitudes that is visited by them, but only the table-lands of the Mexican isthmus, the Andes, and the countries bordering on them, and those which are adjacent to the Caribbean Sea. Mention of earthquakes in these countries occurs in the Spanish historians of the Conquest; but it would seem as if the earthquakes were less destructive formerly than in the last century. In 1717 the town of Guatemala was greatly damaged by an earthquake on the 29th of September; and on the 29th of June, 1773, the town was almost entirely destroyed. Caracas was destroyed by an earthquake on the 26th of March, 1812, when upwards of 12,000 of its inhabitants were buried in the ruins; and the same town experienced, in 1826, another earthquake, which was hardly less destructive. Bogotà experienced a very severe shock in 1827. On the table-land of Quito violent earthquakes are frequent. In 1698, on the 20th of June, Lacatunga and Hambato were destroyed; and on the 4th of February, 1797, the town of Quito was greatly damaged, and Riobamba levelled to the ground. Not less than 40,000 persons are stated to have perished by this last earthquake on the table-land. Lima and the countries about it are likewise subject to frequent and violent earthquakes. The town of Lima was almost entirely destroyed on the 20th of October, 1687, and again on the 28th of October, 1746. In this latter catastrophe the port of Callao was inundated by the sea, and the whole population perished. Arequipa has had its share of earthquakes; but the last violent one occurred in 1725. Copiapò was destroyed on the 11th of April, 1819, and again in 1822. By this last earthquake, which happened on the 19th of November, the town of Valparaiso was levelled to the ground. Santiago has suffered largely from the destructive effects of the earthquakes so frequent in Chile: on the 8th of July, 1730, it sustained great damages. But no place in Chile has so frequently been destroyed as Concepcion. It was first destroyed by the united effects of repeated shocks and the inundation of the sea in 1730, and again in the same manner in 1751. After this the town was rebuilt on another site; but this new town and its port of Talcahuano were entirely demolished on the 20th of February, 1835. A most graphic description of this dreadful earthquake is given in the 'Journal of the Royal Geographical Society of London,' vol. vi. p. 319, &c., to which we are much indebted for several valuable facts and remarks. The inundation of the sea during this calamity may be compared with the narrative of a similar event recorded by Thucydides (iii. 89).

Since the preceding sketch of the circumstances attending earthquakes was first published, great attention has been given to the philosophical investigation of their phenomena; in which Mr. R. Mallet, M. Inst. C.E., F.R.S., and M. Perrey, of Dijon, have taken the lead. From the researches of the first, there is every reason to consider it established that an earthquake is simply "*the transit of a wave or waves of elastic compression in any direction, from vertically upwards to horizontally in any azimuth, through the crust and surface of the earth, from any centre of impulse or from more than one, and which may be attended with sound and tidal waves, dependent upon the impulse and upon circumstances of position as to sea and land.*" Four elaborate

Reports on the facts and theory of earthquake phenomena have appeared in those of the British Association for the Advancement of Science, for the years 1850, 1851, 1854, and 1858, by Mr. Mallet and his son Dr. J. W. Mallet, to which we may refer, as incorporating almost everything that is known respecting earthquakes; and the fourth includes a most valuable bibliography of the subject. Mr. R. Mallet is also the author of the article 'On Observation of Earthquake Phenomena,' in the 'Admiralty Manual of Scientific Enquiry,' 3rd edit., Lond., 1859, p. 325–363, from which the foregoing definition is cited.

From the investigations contained or recorded in these works have resulted the new sciences or departments of science termed SEISMOLOGY and SEISMOMETRY, an article on which, containing also additional facts of earthquake phenomena, will be found in its proper place.

EARTHS. This term is sometimes applied in chemistry to denote the oxides of those metals of which aluminium is a type. The earths are Alumina, Thorina, Glucina, Zirconia, Erbia, and Terbia. The name *alkaline-earths* is, in like manner, applied to Baryta, Strontia, Lime, and Magnesia. Further information respecting these bodies will be found under the respective names of the metals, ALUMINIUM, THORINUM, GLUCINUM, ZIRCONIUM, ERBIUM, TERBIUM, BARIUM, STRONTIUM, CALCIUM, and MAGNESIUM.

EASEL (derived by some from the Teutonic *asel*, or *esel*, an ass), the wooden frame, furnished with a set of moveable pegs, or more convenient rack and sliding ledge, on which pictures are placed while being painted, and which raises or lowers them according to the artist's convenience. Its antiquity is manifest, from its appearance in pictures discovered in Herculaneum. Several modifications have been made in the form of easels and in the apparatus for raising and lowering the pictures, but the principle is the same in all.

EASEMENT (from the French words *aise*, *aisement*, ease), is defined by the old law writers as a service or convenience which one neighbour hath of another by charter or prescription without profit; as a way through his ground, a sink, or the like. It includes rights of way, water-courses, ancient lights, and various other franchises, issuing out of corporeal hereditaments, and sometimes, though inaccurately, is applied to rights of common.

At the common law these privileges (which can only be created and transferred by deed) might be claimed either under an immemorial custom or by prescription; but 20 years uninterrupted and unexplained enjoyment of an easement formerly constituted evidence for a jury to presume that it originated in a grant by deed; except in the city of London, where the presumption of a grant from 20 years' possession of windows was excluded by the custom which required that there should exist "some written instrument or record of an agreement." Nonuser during the same period was also considered an extinguishment of the right, as raising a presumption that it had been released.

By the statute 2 & 3 Will. IV. cap. 71, several important alterations were made with regard to this description of property: 40 years' enjoyment of any way or other easement, or any water-course, and 20 years uninterrupted "access and use of any light to and for any dwelling-house," &c., now constitute an indefeasible title, unless the owner enjoys "by some consent or agreement expressly given or made for that purpose by deed or writing." The same statute also enacts that nonuser for the like number of years (according to the description of the particular right) shall preclude a claim to it. The custom of London is indirectly excluded by this statute.

The easements of the English correspond to the Servitutes of the Roman and the Servitudes of the French and Scotch laws. The servitutes were a class of rights which gave rise to numerous complicated questions. Those of road, water, light, drains, were the principal.

(*Dig.* l. viii. *De Servitutibus*; *Code Civil*, l. ii. tit. 4, *Des Servitudes*; Ersk. Inst., *Servitudes*.)

EAST. The point of the compass which is in a direction at right-angles to that of north and south, and which is towards the *right* hand of a spectator who faces the north. The distinction between east and west must ultimately be derived from a reference to the human body; for we can only define a spectator's *right* hand by saying that it is the hand which is not upon the same side as the heart.

EAST INDIA COMPANY. This association originated from the subscriptions, trifling in amount, of a few private individuals. It gradually became a commercial body with gigantic means, and next, by the force of unforeseen circumstances, assumed the form of a sovereign power, while those by whom it was directed continued in their individual capacities to be without power or political influence; thus presenting an anomaly without a parallel in the history of the world.

The company was first formed in London in 1599, when its capital, amounting to 30,000*l.*, was divided into 101 shares. At the end of the next year the adventurers obtained a charter from the crown, under which they enjoyed certain privileges, and were formed into a corporation for fifteen years, under the title of 'The Governor and Company of Merchants of London trading to the East Indies.' Under this charter the management of the company's affairs was intrusted to 24 members of a committee chosen by the proprietors from among their own body, and this committee was renewed by election every year.

The first adventure of the association was commenced in 1601. In the month of May of that year, five ships, with cargoes of merchandise and bullion, sailed from Torbay to India. The result was encouraging, and between 1603 and 1613, eight other voyages were performed, all of which were highly profitable, with the exception of the one undertaken in the year 1607. In the other years the clear profits of the trade varied from 100 to 200 per cent. upon the capital employed. At this time the trading of the Company was not confined to the joint stock of the corporation, but other adventurers were admitted, who subscribed the sums required to complete the lading of the ships, and received back the amount, together with their share of the profits, at the termination of every voyage.

The charter of the Company was renewed for an indefinite period in 1609, subject to dissolution on the part of the government upon giving three years' notice to that effect. In 1611 the Company obtained permission from the Mogul to establish factories in Surat, Ahmedabad, Cambaya, and Goga, in consideration of which permission it agreed to pay to that sovereign an export duty upon all its shipments at the rate of 3½ per cent.

After 1612 subscriptions were no longer taken from individuals in aid of the joint-stock capital, which was raised to 420,000*l.*, and in 1617-18 a new fund of 1,600,000*l.* was subscribed. This last capital, although managed by the same directors, was kept wholly distinct from the former stock, and the profits resulting from it were separately accounted for to the subscribers.

The functions of government were first exercised by the Company in 1624, when authority was given to it by the king to punish its servants abroad either by civil or by martial law, and this authority was unlimited in extent, embracing even the power of taking life. In 1632 a third capital, amounting to 420,700*l.*, was raised, and its management, although confided to the same directors, was also kept distinct from that of the first and second subscriptions. It is uncertain whether the capitals here severally mentioned were considered as permanent investments or were returned to the subscribers at the termination of each different adventure.

A rival association, formed in 1636, succeeded in obtaining from the king, who accepted a share in the adventure, a licence to trade with India, notwithstanding the remonstrances of the chartered body, of whose rights this was deemed an infringement. Promises indeed were given that the licence should be withdrawn, but these promises were never fulfilled; and after carrying on their trade for several years in a spirit of rivalry which was fatal to their prosperity, the two bodies united in 1650, and thenceforward carried on their operations under the title of "The United Joint Stock." In 1652, the Company obtained from the Mogul the grant of a licence for carrying on an unlimited trade throughout the province of Bengal without payment of duties.

Some proprietors of the Company's stock becoming dissatisfied with the management of the directors, obtained from Cromwell, in 1655, permission to send trading vessels to India, and nominated a committee of management from their own body, for which they assumed the title of "The Merchant Adventurers." The evils to both parties of this rivalship soon became apparent, and in about two years from the commencement of their operations the Merchant Adventurers threw their separate funds into the general stock under the management of the directors. On this occasion a new subscription was raised to the amount of 786,000*l.* In April, 1661, a new charter was granted to the Company, in which all its former privileges were confirmed, and the further authority was given to make peace or war with or against any princes and people "not being Christians;" and to seize all unlicensed persons (Europeans) who shall be found within the limits to which its trade extended, and to send them to England. This formed and continued to be the East India Company.

The acquisition of territorial possessions, the nature of the productions of such territories, and of the trade of the Company, are all explained under the head of HINDUSTAN, in GEOG. DIV.; and in the separate articles BENGAL, BOMBAY, MADRAS, ASAM, SINDE, &c., with the nature of the government up to the alteration made by the 21 & 22 Vict. cap. 106, passed August 2, 1858, by which all the territories heretofore under the government of the East India Company are vested in her Majesty. By the act a new Secretary of State for India is appointed, assisted by a council of fifteen, of whom seven are to be elected by the directors of the old Company, and eight are nominated by the crown. Interest at the rate of 10 per cent. on the capital of the old Company is charged on the revenue of India. Directors are still to be elected, as before, by the proprietors, but their functions extend but little beyond electing the members of the council on occasion of a vacancy, and paying the dividends to the proprietors. All property possessed by the Company in their corporate capacity was also vested in her Majesty, and the troops employed by it were transferred to her Majesty's service, and have become her Majesty's Indian army.

EASTER, Anglo-Saxon *Eastre*, a moveable feast, held in commemoration of the Resurrection; being the most important and most ancient in observance, it governs the whole of the other moveable feasts throughout the year. In the Greek and Latin churches it is called Πασχα, *Pascha*, originally derived from a Hebrew word signifying a passage, which was the name given to the great feast of the Passover, held by the Jews on the same day with that on which our Saviour held his paschal feast. The etymologies of the word Easter have been various.

Bede says it was derived from a goddess called *Eostre,* to whom the people used at this season to celebrate festivals. Wheatley ('On the Common Prayer') says it is from the Saxon *Oster,* to rise; another derivation is from the Anglo-Saxon *yst,* a storm, the time of Easter being subject to the continual recurrence of tempestuous weather.

That the observation of Easter is as ancient as the time of the Apostles seems undoubted. In the 2nd century, however, a controversy arose as to the exact time of its celebration. The Eastern churches kept it on the 14th day of the first Jewish month; the Western churches on the night which preceded the anniversary of our Saviour's resurrection. The inconvenience of the former was, that this festival was commonly held upon other days of the week than the first, or Sunday, which was undoubtedly the proper day. The disputants retained their respective customs till towards the middle of the 4th century, when the rule for the celebration of Easter was fixed by the Council of Nice, A.D. 325. It was ordered to be held on the Sunday which falls next after the first full moon following the 21st of March, or vernal equinox. But the calculation for the full moon of the Calendar does not always follow that for the full moon of the astronomer, as was the case in 1845. For the true method of finding Easter, see the following article.

Brand, in his 'Popular Antiquities,' has given a long enumeration of the sports and observances at Easter in former times, including a few superstitions. The mutual presentation of coloured eggs at this season from friends continues both in the East and in Russia. *Lifting,* originally designed to represent our Saviour's resurrection, is also still practised on Easter Monday and Tuesday in England, in Lancashire and some other counties. Tansey puddings and cakes were anciently eaten in England at Easter.

EASTER, Method of Finding. The importance of this question, in aiding historical reference, is confined to that definition of Easter Sunday which was finally adopted by the Western Church. As this definition is given in the prayer-books of the establishment in a manner which has led to misconceptions, we here give an amended version of that definition, which truly represents the tables of the Gregorian Calendar, being the very tables which the English Church uses. Easter day, on which the rest of the moveable feasts depend, is always the first Sunday *after* the *fourteenth day* (not the *full moon*) of the *calendar moon* (not the moon of the heavens, nor even the mean moon of the astronomers) which happens *upon or next after* the 21st of March, according to the rules laid down for the construction of the calendar; so that if the fourteenth day happen upon a Sunday, Easter day is the Sunday after.

By common consent, it is not the real sun or the real moon which is employed in finding Easter, but the fictitious sun and moon of astronomers, which move uniformly with the average motion of the real bodies: and even these, as we shall see, are only used to construct a *calendar moon* for ecclesiastical convenience. It must therefore never surprise any one to find the Easter of any year not agreeing with the moon to a day, since such a case might (and sometimes must) arise. But the following rules will determine the Easter day of chronologists in any year of the Christian era, which is all that is required :—

First, ascertain the dominical letter, taking the second where there are two. [DOMINICAL LETTER.] Next, ascertain the golden number (year of the Metonic cycle) as follows: add one to the date of the year and divide by 19, the remainder (or if there be no remainder, 19 itself) is the golden number. The following table must then be used, in the manner to be immediately explained :—

	O. S.	N. S.		O. S.	N. S.
March 21 C	16	14	April 9 A	17	15
,, 22 D	5	3	,, 10 B	6	4
,, 23 E	..	..	,, 11 C	..	..
,, 24 F	13	11	,, 12 D	14	12
,, 25 G	2	..	,, 13 E	3	1

,, 7 F	9	7			
,, 8 G	..	..			

O. S. means *old style;* N. S., *new style.*

Having the golden number, and the dominical letter, find out the golden number in the second or third column, according as old style or new style is meant; and look down the first column until the *next* occurrence of the dominical letter comes. Easter day is opposite. Thus the golden number being 13 and the dominical letter F, Easter day is March 31 in the old style, April 7 in the new style.

Example 1.—What was Easter day A.D. 1688 (old style)?

The dominical *letters* are A G. Take the second, G.

$$\begin{array}{l} 1688 \\ 1 \\ \hline 19)1689(88 \\ \quad \text{rem. 17 the golden number.} \end{array}$$

Opposite to 17, under O. S., comes April 9 A, and the next G which occurs is opposite April 15, which was therefore Easter day.

Example 2.—When did Easter day fall, A.D. 1841?

The dominical letter is C.

$$\begin{array}{l} 1841 \\ 1 \\ \hline 19)1842(96 \\ \quad \text{rem. 18 the golden number.} \end{array}$$

Opposite to 18, under N. S., is April 6 E, and the next C is opposite to April 11, which is therefore Easter day.

The following table gives Easter day for every year from 1800 to 1999. Thus in 1873 Easter day is April 13 (a. 13); in 1973 it is April 22 (a. 22).

Some years, such as 1818 and 1845, are made remarkable by Easter Sunday being kept in direct defiance of the statement made in the Act of Parliament (24 Geo. II. cap. 23), by which it is "the first Sunday after the *full moon* which happens upon or next after the 21st day of March; and if the full moon happens upon a Sunday, Easter Day is the Sunday after." The act which makes this statement also prescribes rules; that is, copies the rules of the Gregorian calendar, and the tables constructed from them. According to the rules and tables, Sunday, March 23rd, was Easter Day of 1845. But the full moon was on this very day, at past 8 o'clock in the evening; so that by the explanation, Easter day ought to have fallen on the 30th. The error arises from a mistake and an omission in the Act of Parliament: Easter was never determined by the day of the "full moon," but by the "*fourteenth day* of the moon," which words ought to have been written instead of "full moon;" and, moreover, the moon of the calendar is not the moon of the heavens, but an imaginary moon in advance of it, contrived for reasons we shall presently mention. The definition at the beginning of this article has the mistakes corrected.

We shall in this article give as much of the history of Easter, and of the reformation of the calendar, as may explain the discussions upon this subject, referring for fuller information to an article 'on the Ecclesiastical Calendar' in the 'Companion to the Almanac' for 1845, and to some supplemental information in the same work for 1846. A sharp discussion occurred in 1818, at which period we cannot ascertain that the true explanation was given by any one: the discussion of 1845 was checked by the article first referred to. When it next happens, the same misunderstandings will be repeated, unless either the explanation given by the Act of Parliament be altered in the mean time, or works of reference be made to contain an account free from the usual errors.

The disputes which agitated the Christians of the 2nd century respecting the observance of Easter depended upon two questions:
